DEPENDENCE ON TEMPERATURE OF THE INTERLAYER SPACING OF IRRADIATED GRAPHITES

By B P JACKETS and D J DYSON

The General Electric Company, Limited, Hirst Research Centre, Wembley, Middlesex

MEASUREMENTS of the interlayer spacing, at temperatures between room temperature and − 192° C , of three (unirradiated) graphites of differing crystal perfection, and of one lightly neutron-irradiated *A*-grade graphite have been reported[1] The rate of contraction of each material showed a 'levelling off' with decreasing temperature The graphs of temperature versus interlayer spacing for the various samples were essentially similar but translated parallel to the spacing axis, the less perfect graphites having the larger interlayer spacings at corresponding temperatures

When graphite is irradiated by fast neutrons, changes occur in both the bulk dimensions and the crystal lattice parameters Simmons[2] has developed a relationship between the bulk and crystal dimensional changes, which applies both to thermal expansion and irradiation growth and shrinkage Extension of this relationship to more highly damaged material requires a knowledge of the changes in the crystal thermal expansion coefficient induced by different irradiation doses The present X-ray investigation was designed to determine whether or not the crystal expansion coefficients of heavily irradiated graphites differ from the crystal expansion coefficients of lightly irradiated or unirradiated materials As spacing measurements at high temperatures are not possible (heating above 150° C produces irreversible changes in the lattice parameters owing to thermal annealing of the neutron damage) the lattice contraction on cooling to liquid nitrogen temperature has been studied Owing to the diffuse nature of the diffraction maxima the measurements have had to be confined to determining the comparatively large changes in the interlayer spacing

Three specimens of graphite were irradiated in rigs in the *Dido* Materials Testing Reactor at the Atomic Energy Research Establishment, Harwell The doses experienced by the specimens were determined by the activity produced in nickel by an (*n,p*) reaction Details of the rigs and the relation between nickel dose and damage dose have been given previously by Bell *et al* [3] The irradiation conditions of the samples are given in Table 1

All measurements were made with a Philips diffractometer, type *PW* 1050, fitted with a proportional counter , nickel-filtered copper *K*α radiation was used The diffractometer low-temperature attachment used has been described elsewhere[4]

In Fig 1 the contraction of the interlayer spacing of each sample is shown as a function of temperature , it is evident that the magnitude of the contraction, over the temperature range examined, is substantially

Table 1

Sample code	Irradiation temperature (°C)	Nickel irradiation dose (n v t)
KB/B/BC	200	0 89 × 10^{20}
KB/B/AL	200	1 67 × 10^{20}
KP/B/DI	200	3 72 × 10^{20}

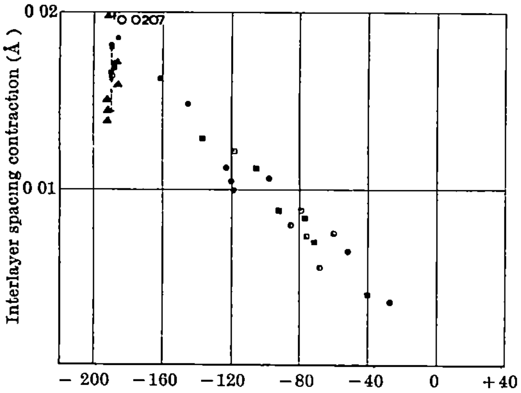

Fig. 1. Contraction of the interlayer spacing of irradiated graphites between 21° C and − 192° C. △, *KP/B/DI*, □ *KB/B/AL*, ○ *KB/B/BC*

the same, within the limits of experimental error, for all three samples. Consideration of only the results obtained at approximately − 190° C reveals, however, a tendency for the contraction to decrease slightly with increasing neutron irradiation dose; this is particularly so if the contraction value of 0.0207 for sample *KP/B/DI* is ignored. This contraction value is appreciably higher than the other five values obtained at this temperature with this sample.

The mean coefficient of expansion in the *c*-direction over the temperature-range from − 190° to 21° C has been calculated for each sample and the values are given in Table 2. Again, if the particularly large value for the contraction of sample *KP/B/DI* is ignored, a small decrease in the expansion coefficient with increasing irradiation dose is found.

An essential similarity is apparent in Fig. 2 between the results for the present irradiated graphite samples and the previously examined[1] unirradiated graphites. It may be seen that the rate of interlayer spacing contraction of all the samples below room temperature is less than the rate of expansion of the unirradiated samples above room temperature.

Table 2. Expansion Coefficients in the *c*-direction over the Temperature-range from about − 190° to 21° C

$$a = \frac{2}{d_1 + d_2} \times \left(\frac{d_1 - d_2}{t_1 - t_2}\right)$$

Sample code	Expansion coefficient (per ° C.)
KB/B/BC	$(25.2 \pm 0.8) \times 10^{-6}$
KB/B/AL	$(23.2 \pm 0.4) \times 10^{-6}$
*KP/B/DI**	$(22.4 \pm 2.8) \times 10^{-6}$
KP/B/DI†	$(21.1 \pm 1.3) \times 10^{-6}$

* Value calculated from the six results obtained for this sample.
† Value calculated omitting the particularly high 0.0207 result.

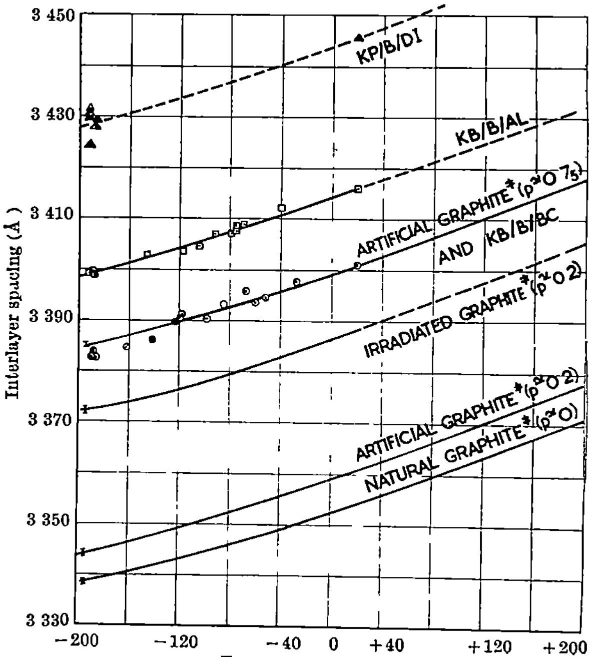

Fig. 2. Interlayer spacings of irradiated and unirradiated graphites as a function of temperature. ‡ Previously examined samples (ref. 1)

Possible differences between the samples in the change in *a*-spacing on cooling have not been investigated, the *a*-spacing change for each sample would be expected to be very much smaller than the *c*-spacing change, because of the much greater bonding forces within the layer planes than between them. Figs. 1 and 2 indicate that there are no marked differences in the magnitude of the *c*-spacing contraction with increasing neutron dose to a nickel-dose of 3.7×10^{20} n.v.t. There is therefore as yet no firm indication that the observed changes[2] in the bulk properties of graphites on irradiation are dependent on changes in the crystal expansion coefficients.

We thank the Reactor Materials Laboratory, Culcheth, U.K. Atomic Energy Authority, for suggesting the investigation and supporting the work. This article is published by permission of the Managing Director of the Reactor Group of the Authority.

PARENT BODY HYPOTHESIS FOR ORIGIN OF TEKTITES

By ERNST W. ADAMS and ROBERT M. HUFFAKER

Geo. C. Marshall Space Flight Center, National Aeronautics and Space Administration, Huntsville, Alabama

According to Chapman *et al.*[1], observation of australites shows that they were derived from bodies of revolution and in the majority of cases from spheres. These authors presented conclusive experimental proof that glass spheres, when placed in an electric arc-jet tunnel and exposed to heating-rates of the order of those experienced in hypersonic flight become strikingly similar to button-type australites. This similarity comprises, first, a peculiar system of ring waves on the ablated front face, secondly, a coiled circumferential flange made of solidified melt, and finally, opposite to the stagnation point and enclosed by the flange, a spherical remainder of the original surface shape The anterior surface of button-type australites was thus formed by aerodynamic ablation acting on initially cold glassy spheres which, therefore, entered the atmosphere of the Earth at high altitude

According to observed mass loss-rates and according to results of trajectory and ablation analysis[2], this entry took place in a nearly horizontal direction with velocities between 6 5 and 11 2 km /sec in case of average-size buttons (11 gm initial weight[3]) Trajectory analysis indicates that bodies as small as tektites hurled up from sea-level altitude cannot traverse the atmosphere to re-enter under these conditions A simple calculation yields an initial deceleration of 96,000g for a solid glass sphere of 1 3 cm radius leaving the surface of the Earth at 8 km /sec This proves that ejecta hurled up by impact on the surface of the Earth cannot form a tektite cluster Because of the presence of nickel–iron spherules in some tektites[4], meteor impact and not volcanic eruption caused tektite flight Ejecta hurled up by impact on any extra-terrestrial body in the solar system generally stay in space for very long periods of time and, if approaching the Earth, do not arrive in a dense and short-lasting shower[5], as is demanded by the existence of a few and relatively small tektite-strewn fields These arguments show that tektite showers could not have originated as clusters of individual tektites by impact on the Earth or any other celestial body

The existence of limited tektite-strewn fields could be explained if tektites were released as liquid fragments from the ablating surface of a hypothetical parent body in hypersonic flight in the Earth's atmosphere Hardcastle[6] and Hanuš[7] stipulated that the surface of a stony meteor melted during hypersonic flight in the atmosphere and sprayed liquid droplets, which gave rise to the characteristic forms of tektites while cooling off In general, however, aerodynamic heating-rates in high-speed flight are so great that the molten layer on the surface of a stony meteor is extremely thin, because of the low thermal diffusivity of stone and the almost immediate evaporation of the melt O'Keefe[8] pointed out that the evaporation-rate of the melt might become sufficiently small if a grazing orbit with small instantaneous heat transfer-rates is considered, like that of the Cyrillid shower

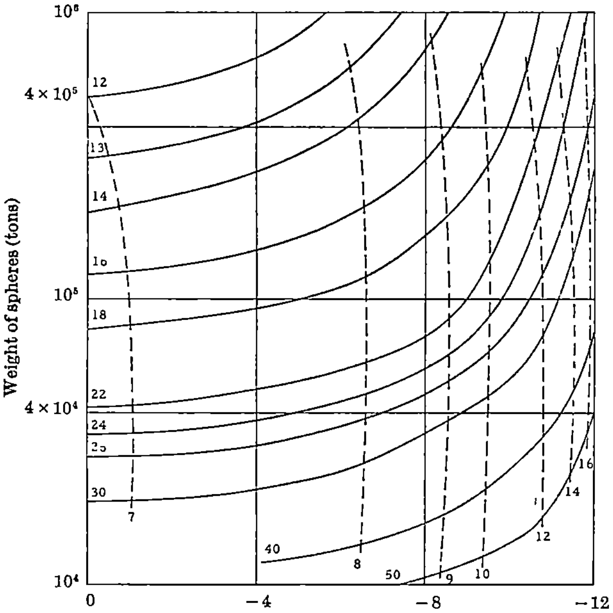
Aerodynamic Heating and Ablation of a Parent Body

By applying a calculation method (ref 9 and unpublished reports), we have examined the ablation of stony and glassy objects in high-speed flight in the atmosphere of the Earth The physical aspects of the underlying ablation processes are summarized as follows Since the thickness of the hot gas layer between the shock front and the surface increases together with the cross-section of a body in supersonic flight, the obviously large parent bodies are predominantly heated by radiation emitted from the hot gas layer, whereas bodies as small as tektites essentially experience convective heating only Detailed calculations show that the extremely high radiation-rates of as much as 10^4–10^6 kcal /m ^{2} sec , which are incident at the surface of a large parent body in hypersonic flight, cause the surface to boil If the material is opaque to thermal radiation, the heated layer beneath the rapidly receding surface has a thickness of considerably less than 1 mm , obviously, only negligible amounts of liquid material could then be released from the parent body The calculations show, however, that a layer of several cm thickness reaches temperatures of 3,000°–5,000° K if the material is sufficiently transparent to thermal radiation In one special case, the thickness of the radiatively heated layer turned out to be 5 cm for the absorption coefficient $\alpha = 100$ (1/m) of clear window glass and 0 6 cm for $\alpha = 1,000$ (1/m) Vapour nuclei are then formed at non-homogeneous spots in the glassy melt Unless strong temperature gradients normal to the surface exist in the melt, there is no force present which drives the bubbles towards the surface The outer portions of the radiatively heated layer, therefore, consist of a spongy glass melt which offers little resistance to being removed from the parent body by the air forces acting in hypersonic flight Since this mechanism rests on the existence of sufficiently high temperatures in the spongy layer, the detached fragments possess low viscosity and break up readily in the air stream The outlined process implies that the parent body consists of a glassy material the chemical composition of which is similar to the one of tektites This glassy substance cannot be generated by fusion of siliceous stone due to aerodynamic heating, because the transparency of stone is too low as to allow a radiatively heated layer of sufficient thickness (see the numbers already quoted)

Terrestrial Origin of Parent Body Flight

If tektites became detached from an ablating glassy parent body which was hurled up by some violent natural event from the Earth's surface, the parent body must have been sufficiently rigid at the time of its departure in order to avoid immediate disintegration The initial speed must have been sufficiently high and the initial trajectory angle sufficiently shallow if an area of the size of Australia is to be covered by fragments of this body or a cluster of large bodies hurled up by the same event Fig 1 presents exit speed and exit angle at 150 km altitude above sea-level for non-ablating spheres of specific weight 2 4 gm /cm ^{3}, which depart from sea-level altitude at an angle of 5° relative to the horizon The ascending spheres must exit from the atmosphere with at least the previously derived minimum entry speed[2], 6 5 km /sec , of button-type australites if average-size buttons are released from these spheres According to Fig 1, the exit speed of 8 km /sec requires an initial speed of 24 km /sec for a body of 46,000 tons and 12 km /sec for a body of 1 05 × 10^6 tons Solid fragments hurled up from terrestrial volcanic eruptions or impact craters are known to be considerably smaller than 10^4 tons and to have travelled only short distances Since initial speeds at sea-level altitude in excess of 12 km /sec cause very high ablative mass loss-rates, the parent body shrinks rapidly

As compared with the results in Fig 1, which pertains to non-ablating bodies, considerably larger initial weights and velocities are necessary to obtain an exit speed $\geqslant$ 6 5 km /sec at 150 km altitude The extremely large initial acceleration-rates, going together with the initial flight speeds under discussion, subject the impact-ejecta to surface and internal stresses which cause immediate disintegration, regardless of whether the material is in the liquid or in the solid state The presented arguments show that individual tektites and their hypothetical parent



Exit angle (deg.) relative to Earth's horizon at altitude H = 150 km. The trajectory angle θ is negative for ascending flight period

Fig. 1. Exit velocity and exit angle of non-ablating spheres starting from sea-level altitude at the initial angle $\theta = -5°$ relative to horizon. —, Curves of constant initial velocity (km./sec.) at sea-level (H = 0 km.), – – –, curves of constant exit velocity (km./sec.) at exit altitude (H = 150 km.)

bodies could not have been hurled up from the surface of any planet covered by a dense atmosphere, unless one stipulates an extremely violent natural event of such magnitude as to cause the atmosphere to be essentially 'blown out'. Urey[5] has suggested a comet–Earth collision as being a possible origin of the tektites.

Extraterrestrial Origin of Parent Body Flight

Characteristic features of the Indomalayan and Australian tektite-strewn fields can be explained if a parent body of extraterrestrial origin in hypersonic skipping flight in the atmosphere of the Earth is considered. The vapour bubbles, in spongy droplets which skip together with the parent body, expand continuously in ascending flight because of the decrease of the external pressure. The bubbles, correspondingly, tend to burst under this condition, and surface tension converts sufficiently small droplets into relatively compact glassy spheres. Since the majority of the australites were derived from glassy spheres[1,3], the described ablation mechanism implies that the parent body carried out a skipping flight pass in the Earth's atmosphere and released the australites during the ascending flight phase so that they could exit together with the parent body.

The droplets, which became detached from the parent body and did not exit from the atmosphere, remained in the liquid state until they slowed sufficiently in the denser layers of the atmosphere. Because of the increasing pressure forces exerted by the air stream in descending flight, surface tension did not shape these droplets which, at the same time, remained spongy. Due to a lack of well-defined shape, the non-skipping droplets in general did not possess stable flight attitude so that traces of previous melt flow should appear only in exceptional cases on the solidified surfaces. Since the relatively frothy indochinites and philippinites usually do not possess any well-defined shape and scarcely any markings of melt flow, it may be concluded that these groups of tektites from the Indomalayan strewn field became detached from the parent body and descended immediately without a preceding skipping phase.

Liquid droplets released during the ascending flight phase of a skipping parent body may exit from the atmosphere with any vertical velocity component between zero and the one of the parent body. The droplets take spherical shape only if they fly outside the atmosphere for a sufficient period of time. The necessary minimum flight time outside of the atmosphere decreases together with the size of the droplets, and thus also the necessary vertical component of exit speed.

The mass loss of the smallest discovered button-type australites (1.4 gm. initial weight[3]) correspondingly varies in the limits 20–80 per cent. Fig. 2 of ref. 2 indicates that a mass loss of 20 per cent in case of a button of 1.38 gm. initial weight requires an entry speed of less than 5–7 km./sec. This entry speed is considerably smaller than the minimum velocity at which an extraterrestrial object arrives at the Earth. In addition to the previously presented argument pertaining to the size of the strewn fields, the existence of small button-type australites with mass losses of ⩾20 per cent confirms the parent body hypothesis and rules out, for example, direct departure of a cluster of spheres from the Moon. Droplets which are too large to be shaped by surface tension, or which do not stay outside of the atmosphere long enough, cannot take spherical shape and may account for the australites which were derived from general bodies of revolution, for example, the canoe-shaped forms[3].

The droplets were closely spaced in the parent body's wake at the time of their release. The pressure fields surrounding the individual droplets, therefore, induced velocity components normal to the flight direction of the parent body. This, together with turbulence in the wake of the parent body, as pointed out by O'Keefe[8], explains why droplets released from a parent body can cover strewn corridors of some lateral extension along the projection of the parent body's trajectory. The width of the Indomalayan strewn field possibly cannot be explained by these two effects. It may be necessary, therefore, to assume that the parent body broke up during a first skipping pass through the atmosphere.

Conclusions

Experiment[1] and analysis[2] indicate that button-type australites were derived by aerodynamic heating from initially cold glassy spheres which, in case of average-size specimens, entered the atmosphere in a nearly horizontal direction between 6.5 and 11.2 km./sec., the lower limit, 6.5 km./sec., is demanded by the observed mass loss, 70–90 per cent of average-size buttons. Trajectory analysis shows that terrestrial origin of the spheres is impossible. Since the smallest discovered buttons[3], according to ablation analysis[2], must have entered at less than 7 km./sec., extraterrestrial origin of such a cluster is impossible. The existence of limited tektite-strewn fields can be explained if tektites were released as liquid droplets from the ablating surface of a hypothetical parent body in skipping flight through the Earth's atmosphere. Ablation analysis shows that this parent body must consist of a glassy substance, which cannot be generated by fusion of siliceous stone due to aerodynamic heating Terrestrial origin of such a parent body, even when the material is not in the liquid but in the solid state, would require a violent event of such magnitude as to be very unlikely to have ever occurred

We thank Dr John A O'Keefe of the Goddard Space Flight Center (National Aeronautics and Space Administration) and Mr Werner K Dahm of the Marshall Space Flight Center (National Aeronautics and Space Administration) for useful discussions The assistance of Mr Verkuel N Eubanks for the 7090 computer programming is gratefully acknowledged

APPARENT SOLAR CONTROL OF THE EFFECTIVE CAPACITY OF A 110-V. 170 AH LEAD-ACID STORAGE BATTERY IN AN 11-YEAR CYCLE

By D R BARBER

formerly Superintendent, Norman Lockyer Observatory, University of Exeter

IN March 1914 a Tudor storage battery of 60 cells—each of 170 Ah nominal capacity—was installed at the Norman Lockyer Observatory to supply direct current for lighting and instrumental control The cells are housed within a stone-walled building, with asbestos-tiled roof, the windows of which on the south and west walls are glazed with painted glass (Fig 1) Current is fed to the buildings and telescopes via an overhead grid of approximately L-shaped outline, the lengths of the major and minor arms being 84 and 45 yards respectively

During the 40-year period of its operation, both sets of plates were replaced in 1933, and positive plates again in 1952 Apart from these two interruptions and a period of inactivity during the First World War, the battery has been operated continuously during the whole of its life to date under reasonably constant and light loading conditions

Each unit cell has three positive and four negative plates of dimensions 18 × 30 cm Charging is by means of a direct-coupled Diesel generator, and the battery is re-charged whenever the specific gravity of the pilot cell has fallen to 20 points below the fully charged value The above range of acid density represents about one-half of the maximum permissible drop for this type of cell

Since 1921 a continuous log has been kept of the date of each re-charge , and subsequent to 1946 detailed records of duration of charge, average charging current, and generator voltage are available also No detailed records of the loading are kept, the control board not being equipped with integrating meters It can be stated, however, that prior to December 1938, when a small 110-V 250-W refrigerator was installed, the demand on the battery had been exceptionally light , and apart from intermittent extra loading up to a maximum of 5 amp during night observing, the daily requirements are very constant also Thus throughout its long service the battery has been consistently under-loaded, the actual discharge-rate being such as to simulate 'shelf-life' conditions for this type of cell This point is emphasized as being particularly important in relation to the effects now to be described

Casual reference to the engine-room log book (by Mr A J Denner, attendant in charge of the electrical equipment) in 1946 brought to light what appeared to be a periodic fluctuation in the total number of charges given to the battery in successive years The amplitude was surprisingly large, the ratio of extreme maximum to minimum annual totals being as high as 3 1 On a closer inspection of the data it was seen that the period of fluctuation was close to 11 years, the annual total appearing to show a similar trend to the Zurich sunspot number, R_Z, with a lag of 1–2 years

Fig 2*b* depicts the sequence of annual charge numbers over the 40-year period, 1921–60 The upper inset (*a*) shows the corresponding march of

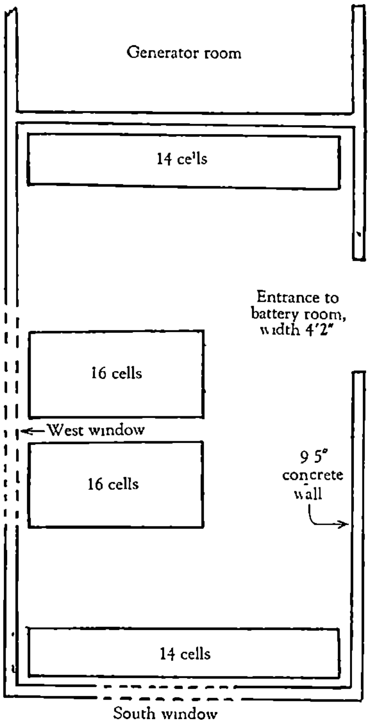

Fig 1 Sketch plan of battery room layout Each window measures 4 ft 2 in by 3 ft and has 18 glass panes 5 in by 10 in covered with white paint At certain times of year some cells near the windows are exposed to diffused sunlight The roof is covered with corrugated asbestos sheet underlaid with 'Ruberoid'

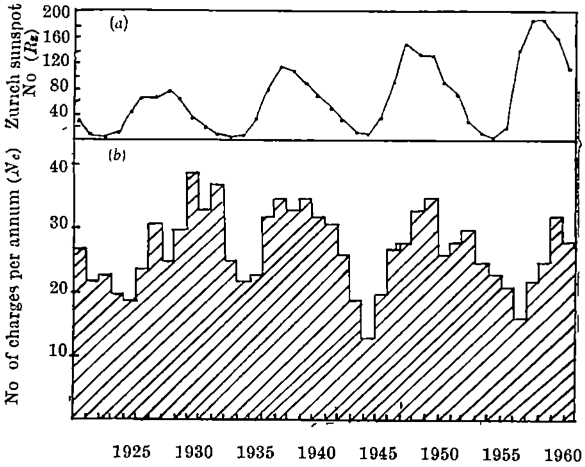

Fig 2 Comparison of curve of annual sunspot numbers (*a*) with secular variation of annual charge number (*b*)

sunspot (R_z) numbers for the same interval, covering approximately three and one-half 11-year cycles It will be noticed that the charge number lags behind sunspot activity by 1 or 2 years Taking the latter into account, the general similarity between the two plots is indeed striking Such an effect appearing most unlikely, it was decided to undertake a rigorous statistical treatment of the material to ascertain whether or not the apparent parallelism of the two curves was really significant

Coefficients of correlation, with their probable errors, were computed for a series of phase differences (relative to sunspot activity) of 0, 1, 1 5, 2 and 3 years The results are give in Table 1

Table 1 ANNUAL CHARGE NUMBER VERSUS ZURICH SUNSPOT NUMBER CORRELATION COEFFICIENTS, AND PROBABLE ERRORS FOR FIVE DIFFERENT TIME LAGS

Time lag (years)	0	1 0	1 5	2 0	3 0
Coefficient *r*	+ 0 25	0 46	0 56	0 46	0 30
P E	±0 10	0 09	0 08	0 08	0 10

It is evident that the best fit of the two parameters occurs for an assumed lag of 1 5 years with a maximum value for the correlation coefficient of + 0 56 ± 0 08 The corresponding values for lags of 0 and 3 years are each about one-half of the maximum

Since the available data cover a sufficiently long period to yield 38 degrees of freedom, the correlation obtained by assuming a $1\frac{1}{2}$ year lag is statistically significant for $P < 0\ 001$, whereas the values of *r* for both 0- and 3-year lags are barely significant at the 0 05 level Thus, it can be said with some confidence that the observed association between the annual trends of frequency of battery charges and sunspot number is highly significant when account is taken of the eighteen-month lag in the battery response Nevertheless it should be stated that there is no implication of a causal relationship between battery response and sunspot activity Indeed, it is highly improbable that any solar relationship to the observed effect will be a direct one A more likely explanation is that the mechanism responsible for the effect is itself dependent on some geophysical phenomenon—for example, some form of ionospheric control the magnitude of which is governed by the prevalent level of sunspot activity

Confirmation of the reality of the mean phase-lag of $1\frac{1}{2}$ years was obtained by first averaging the annual charge totals for years falling at approximately the same phase of each 11-year sunspot cycle The mean values of charge number so obtained were then plotted against corresponding mean values of Zurich number to form a time sequence The resultant plot, shown in Fig 3, reveals a distinct hysteresis loop (broken curve), the charge number for a given value of sunspot number ($R_z = 57\ 5$) being higher during the declining period of spot activity by about 10 charges (Fig 3, *A*, *B*) If now the monthly totals of battery charges from which the annual totals were computed are now re-grouped to allow for the assumed $1\frac{1}{2}$-yr lag, it is found that the dispersion of the observations into two branches disappears, the points now falling on a single curve the equation of which is

$$N_R = N_0\ (1 + a\ R_z + b\ R_z^2)$$

where N_0 is the mean annual charge number for Zurich number, $R_z = 0$, and *a* and *b* are empirical constants A 'least squares' fit of the observed values gives $N_0 = 15\ 7, a = 4\ 0 \times 10^{-1}$, and $b = -2\ 4 \times 10^{-3}$

Since the single curve passes through a flat maximum at $R \simeq 85$, the computed annual charge number in years for which the Zurich number exceeds this value will be ≤ 32 From 1948 onwards successful predictions of N_R from estimates of R_z have been made to within ± 3 charges without exceptions

These results suggest that the ultimate effect of the external controlling factor—whatever it may later prove to be—is to diminish the effective capacity of the electrical storage system during periods of maximum solar activity by an amount equivalent to about 36 Ah, or ~ 30 per cent of the effective capacity of the cells under the conditions of usage stated previously

An additional feature shown in Fig 2*b* is the association of *decreasing* maximum values of charge number in each sunspot cycle with *increasing* maximum sunspot number This is evident when these maximum values are tabulated in sequence as in Table 2

Table 2 SUNSPOT CYCLE*

No	14*b*	15*a*	15*b*	16*a*
Max R_z	77 8	114 4	151 6	(189 5)†
Max N_c	39	35	35	(32)†

* See *Observatory*, 67, 183 (1947) † Provisional values only.

This result again illustrates the diminished effect of the external factor on the battery at levels of sunspot activity in excess of $R_z \simeq 85$, and may indeed aid in discovering the ultimate nature of the mechanism responsible for the effect

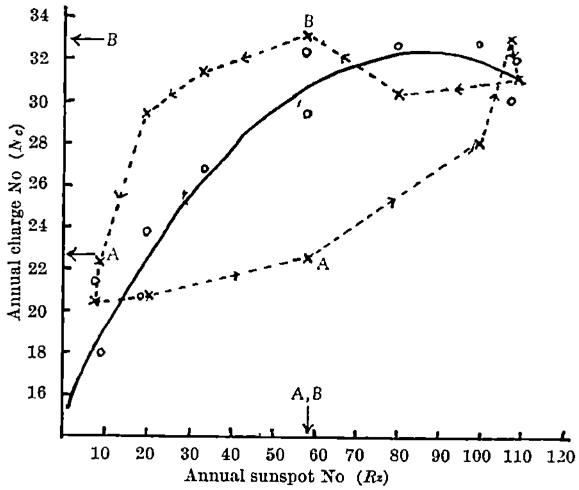

Fig 3 Plots of mean annual charge number versus mean annual sunspot number for three sunspot cycles, 1923–54 ×, uncorrected charge numbers, O, 'least-squares' values after correction for $1\frac{1}{2}$-yr lag of charge number behind sunspot number

It would be of interest to arrive at some quantitative estimate of the actual amount of additional energy imported to the storage battery during years of high solar activity Although no data other than charging frequency exist for the interval 1921–46, it is fortunate that from this latter year onwards detailed records are available for each year up to the present Thus the total annual quantity of electricity generated is known to within ± 0 05 kAh

The situation in regard to the supply side of the system is less satisfactory In the absence of recording meters, no quantities are directly available from which to ascertain annual loads However, the major contribution in each year since 1939 is the load taken intermittently by the 110-V 250-W refrigerator , and tests of this unit have been made which enable its annual load to be computed within close limits To this must be added the load imposed by lighting, light power, and heating circuits that seldom exceeds *in totem* that consumed by the refrigerator alone

Thus it has been possible to assess the supply loading, Q_c, for each year subsequent to 1954 with an uncertainty of ± 0 1 kAh These data, with the corresponding quantities of electricity generated, Q_g, appear in Table 3 In the third row of Table 3 there is entered the nett excess Q_e for each year from 1946 to 1960

Table 3 N L O 110-V 170 AH STORAGE BATTERY OF 60 CELLS
Electrical balance sheet, 1946-60
(Unit = 1 kAh)

Year	1946	1947	1948	1949	1950	1951	1952	1953
Q_g	3 32	3 82	4 36	4 28	3 32	3 70	3 96	3 49
Q_c	2 75	2 95	2 99	3 06	2 49	2 96	2 98	3 01
Q_e	0 57	0 87	1 37	1 22	0 83	0 74	0 98	0 48

Year	1954	1955	1956	1957	1958	1959	1960
Q_g	3 42	3 06	2 48	3 32	3 57	5 63	5 10
Q_c	2 78	2 97	2 29	3 02	2 93	4 69	4 24
Q_e	0 64	0 09	0 19	0 30	0 64	0 94	0 86

This period includes the 1947 maximum and 1954 minimum of sunspot activity , and the years 1952–53 when the positive plates of all cells were renewed, and 'booster charges' afterwards given The latter addition has been allowed for in estimating the tabulated values of Q_g entered in Table 3 It is of further interest to note that the re-platal carried out in 1952, like that of 1933, does not appear to have affected the run of annual charge number over the relevant solar cycle Indeed no trace of any discontinuity appears in either instance

The striking similarity in the trends of excess electricity generated per annum, and annual sunspot number is clearly revealed in the above data The Q_e values first rise to a maximum of 1 37 kAh one year after the 1947 sunspot maximum, afterwards falling, with superposed minor fluctuations, to a minimum value of 0 1 kAh in 1955, one year after sunspot minimum It is uncertain whether the secondary maxima that occur in 1952 and 1954 are evidence of peak values in the external controlling factor, or are internal effects associated with the renewal of the positive plates

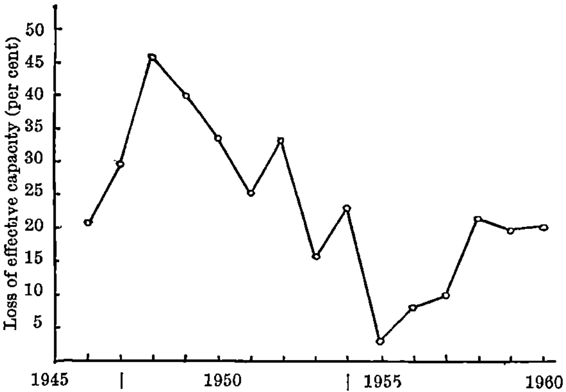

Fig 4 Plot of annual percentage loss of effective cell capacity, 1946–60, exhibiting increased storage efficiency with waning solar activity The period includes the sunspot maximum of 1947 and minimum of 1954

As is clearly shown in Table 3, the fact that in years of high solar activity an appreciable excess of electricity is required at each charge to restore the cells to a fully charged condition implies a loss of effective capacity that appears to be controlled by some unknown and intermediary factor

One useful way of defining this loss is in terms of the ratio (excess electricity supplied/electricity consumed), making use of the relation, percentage loss of effective capacity = 100 (Q_e/Q_c) Annual values of the percentage loss so computed, when plotted versus epoch as in Fig 4, strikingly reveal the changes just described

These detailed results thus confirm the general conclusion derived from the earlier examination of the charge frequency data, namely, that in years of high solar activity the battery loses ~ 30 per cent of its electrical capacity.

The question now arises, does this loss of storage capacity reveal the presence of an internal 'self-discharge' subject to a cyclic variation in step with the 11-yr sunspot cycle ? To attempt an answer, we may first note that in a year of maximum loss of capacity (1948) a total of 1 37 kAh was required to maintain the battery in operation A simple calculation then shows that this corresponds to a continuously flowing leakage current of ~ 0 25 amp or ~ 2 μamp per sq cm plate surface for each cell Considered as an external leakage current, this value is quite unrealistic since careful checks have established that, even under conditions of 100 per cent relative humidity, with heavy and continuous rain falling, the leakage current from the transmission poles to ground never exceeds 1,000 μamp , while in normal conditions (relative humidity <95 per cent) this value falls to $\leqslant 100$ μamp Thus it is obvious that external leakage alone cannot possibly account for the cyclic fluctuation in effective capacity actually observed

Consequently we are forced to look elsewhere for a mechanism capable of providing the observational facts

To this end a large number of experiments have been carried out with small capacity (40 Ah and 4 Ah) lead-acid cells in glass boxes Some of these have included tests with lead, and other forms of direct shielding , and others have been designed to investigate the possible role of incident radio-frequency fluxes on the cells In all instances to date, the results can be regarded as inconclusive evidence The exact nature of the control thus remains unknown but certain of the results may yet prove fruitful in further attempts to elucidate the problem

For example, in some experiments carried out at the suggestion of Dr C E R Bruce (Electrical Research Association) a 2-V cell was first fully charged and then discharged through a constant load of 21 ohms (this value was chosen deliberately so as to give an integrating time of approximately the same length, 2–3 weeks, as that for the large battery) while connected through small capacitors to the Observatory's 110-V positive supply line, and to

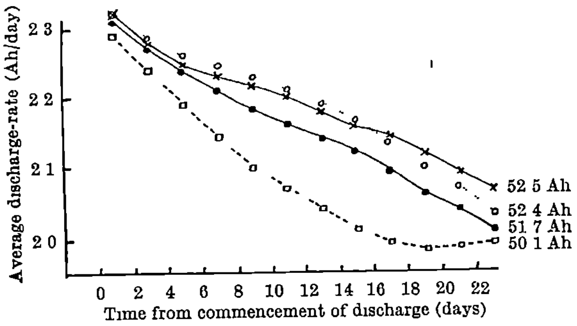

Fig 5 Representative daily discharge curves for 2 V 40 Ah cells under different test conditions ●, normal operation, cell in air, ×, cell shielded with 1-in -thick lead castle, ☐, cell in air, but connected to 110-V line 'aerial', ○, shielded cell connected to 'aerial' (Effective amp -hr capacities under test conditions are entered alongside each curve)

earth If the transmission lines act as a resonant receiving system for very-low-frequency radio-waves, small differences in the effective capacity of the cell might result These would be apparent as differences in the shape of the voltage-time discharge curves when the cell is alternately connected to, and disconnected from, the line 'antenna' Six separate tests gave variable results In three of these a positive result was obtained, the effective capacity decreasing by ~4 per cent when the discharging cell was connected to the 110 V line In two other tests no significant difference was noted, while the sixth test gave a negative result—the capacity was slightly increased when the cell was discharged while connected to the line 'aerial' This sequence of differential tests extended over the period June–September 1960, and it may be argued that the differences shown in the results might well have been due to a seasonal variation of the external controlling factor the constancy of which was assumed throughout each test

A second series of 'aerial' tests, similar to those already described, but with the cell shielded with lead, gave effects of smaller magnitude

In an earlier series of experiments with the same type of cell (1957–59) the test cell was enclosed in a castle of lead having walls 2 5 cm thickness A control cell was operated alongside, in air Several experiments, using the same cell, both screened and unscreened, indicated a gain of a few per cent in the electrical capacity when screened while discharging through a 21-ohm resistor as compared with the discharge curve in air But similar tests of equal weight showed either no significant capacity change, or an actual loss of effective capacity when screened with lead Again, since it was not possible to eliminate the effect of any seasonal variation in the controlling factor, no firm conclusions can be drawn from these experiments They do, however, suggest that in general the effect of radiation screening is to increase the effective capacity of the discharging cell

Tests were also made with very small cells (4 Ah nominal capacity) with, and without, lead screens In this instance it was impracticable to use the same integration time as was used in the other tests, and each experiment was restricted to an overall discharge time of 48 hr No significant differences were found as between screened and unscreened cells This negative result implies that the integration time was in all cases insufficient to allow the effect to build up

Some typical results of the tests made with the 40 Ah cells are depicted graphically in Fig 5 The four curves illustrate the behaviour of the cells under the various conditions cited, and convey an idea of the magnitudes of the effects observed From the results of the foregoing laboratory tests, it would appear that screening from incident low-energy particle radiation may lead, at times, to an increase of the normal cell capacity, while the absorption of very-low-frequency radio radiation may effect the reverse Both effects, however, must obviously be associated with exceedingly small energy exchanges, and it is not easy to visualize any electrochemical reaction capable of producing a sufficiently large change in the electrical capacity of the system to yield an amplification of at least 10^5

However, Piccardi[1] has reported the existence of a world-wide cosmic influence on the rate of precipitation of a suspension of bismuth oxychloride in distilled water He has found also that the cosmic effect is quite similar to that obtained when the precipitation vessel is subjected to a flux of 10 kc /s radiation from a nearby laboratory transmitter

If indeed we are concerned here with a variant of the Piccardi effect, perhaps attributable to radio-noise of terrestrial origin, it is not unreasonable to postulate an indirect solar control of the flux intensity via the lower ionosphere, with an approximately 11-yr periodicity Nevertheless, any approach along the lines just indicated must be regarded as purely speculative in the absence of definite evidence of a specific controlling factor

Summing up the more important features of the observations reported here, four facts appear very pertinent (1) a statistically significant and cyclic variation of the effective capacity of the Observatory's 110-V 170-Ah storage battery with a mean period of 11 yr is evident throughout the forty-year period for which records are available, (2) the fluctuation is seen to follow the 11-yr sunspot cycle with a mean lag of 1½ yr, the effective storage capacity decreasing with rising sunspot number to a minimum at around $R_Z = 85$, thereafter increasing slowly, (3) the loss of electrical capacity, which in 1948 amounted to nearly 50 per cent of the nominal value, would appear to be controlled by an external factor, the exact nature of which is not known A long integration time—at least two to three weeks—coupled with very light loading of the battery appears necessary to reveal the effect, (4) experiments with small capacity (40 Ah) cells, discharged at rates comparable with that of the large storage system, have been made with the cells screened with lead, and coupled to a line 'aerial' system tuned to very-low-frequency radio waves Although the results cannot be regarded as conclusive they point to the possibility that both particle and wave radiations may be involved in the unknown factor controlling the performance of the 110-V battery

Clearly much more experimental work is necessary to elucidate this novel problem But it is felt that publication of the facts already available is justified, for the following reasons

First, a search of the likely literature, coupled with numerous inquiries, has failed to bring to light a prior publication of results similar to those described here, and secondly, it is hoped that publication at this stage may encourage other workers—perhaps more familiar with the complex physico-chemical reactions of the lead-acid cell—to pursue the problem to a satisfying conclusion

MEASUREMENT OF ELECTRON DENSITIES IN THE IONOSPHERIC D-REGION AT THE TIME OF A 2+ SOLAR FLARE

By J. S. BELROSE and E. CETINER*

Defence Research Telecommunications Establishment, Ottawa

A NUMBER of workers[1,2] have computed ionospheric *D*-region electron densities at the time of sudden ionospheric disturbances. The intensity distribution of the ionizing solar flare radiations causing the sudden ionospheric disturbance is not known precisely, and there are uncertainties in the values of ionospheric ionization and loss coefficients, as well as in the knowledge of the *D*-region constituents. This article reports a measurement of electron densities in the *D*-region made near the peak of a sudden ionospheric disturbance, during a class 2+ flare on March 1, 1962. The sudden cosmic noise absorption effect observed on a 30 Mc./s. polar riometer at Ottawa is shown in Fig. 1. The noise burst associated with the flare partially obscured the absorption, which is, however, clearly evident. From the sudden cosmic noise absorption record, the timing and amount of absorption can be clearly established, but only indirectly can the height where the absorption occurs be inferred. The sudden ionospheric disturbance began at 16 38 U.T. (11 38 E.S.T.), reached a maximum at 16 47 and finished by 17 50.

It is difficult to devise ground-based experiments which give direct evidence about electron densities and collision frequencies in the *D*-region. In this investigation, the Gardner and Pawsey[3] experiment was used. When pulses of frequency greater than about 1 Mc./s. or so are returned vertically from the ionosphere, they are usually reflected from above the *D*-region. If, however, the power is very great, it is possible to detect weak echoes (reflexion coefficients of 10^{-3}–10^{-7}) from heights of 50–100 km. These echoes are usually, but not invariably, accompanied by much stronger echoes from greater heights. Previous workers[3-5], who have observed such reflexions, have experienced difficulties because of insufficient transmitter power, lack of discrimination between magneto-ionic components, and oblique reflexions. At this establishment, an attempt was made to overcome these limitations by using high-transmitter powers and directive antenna systems. Two frequencies are used: at 2.66 Mc./s. four-dipole circularly polarized antennæ are used for transmission and reception, and a transmitter power of 1,000 kW.; at 6.275 Mc./s. a similar antenna system is used for transmission, but for reception a 128-dipole circularly polarized antenna array is used covering 9 acres of ground, and a transmitter power of 100 kW.

The amplitude of radio waves partially reflected from *D*-region ionization irregularities is determined partly by the reflexion coefficient of the scatterers, and partly by absorption in the region below the scatterers. Thus, if R is the amplitude of the extraordinary or ordinary wave reflected from a scatterer at height h, and A is the effective reflexion coefficient of the scatterer, then

$$\frac{R_e}{R_0} = \frac{A_e}{A_0}\exp[-2\int_0^h (K_e - K_0)\mathrm{d}h] \qquad (1)$$

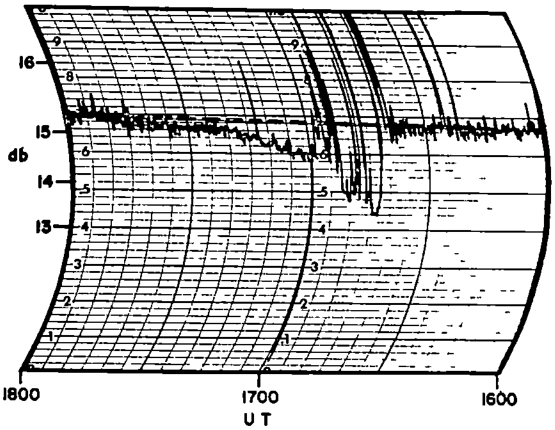

Fig. 1. Record of the sudden ionospheric disturbance absorption (sudden cosmic noise absorption) observed at 30 Mc./s. using a polar-directed antenna

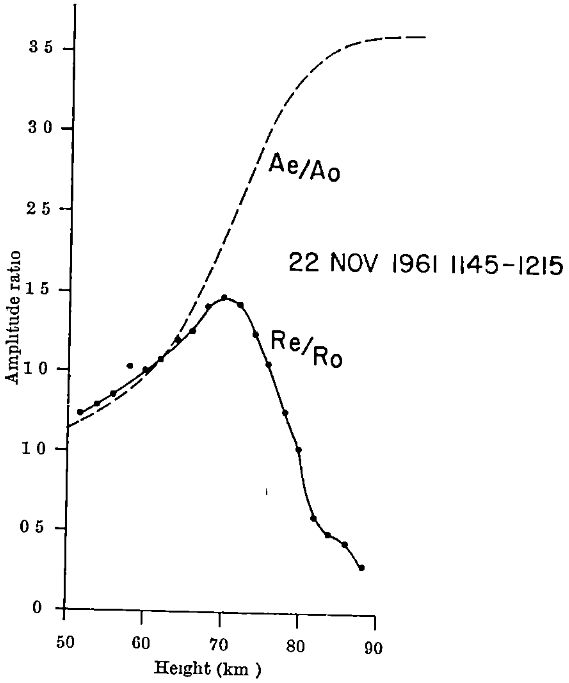

Fig. 2. Function A_e/A_0 and R_e/R_0 with height for 2.66 Mc./s. for a quiet day, November 22, 1961. Average results for 11 45–12 15 E.S.T.

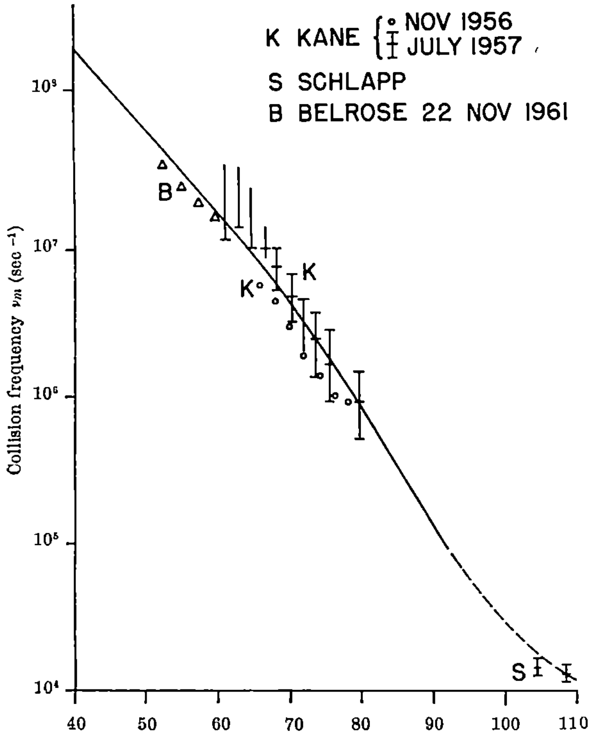

Fig. 3. Collision frequency of electrons ν_m (collision frequency of monoenergetic electrons) plotted against height for the best theoretical and experimental data available

where K is the absorption coefficient integrated up to the scatterer and back. Making certain simplifying assumptions, the ratio A_e/A_0 depends only on the wave frequency ω, the gyro-frequency ω_H, and the electron collision frequency ν_m[6]. Hence the integrated differential absorption can be determined as a function of height, and electron density profiles can be computed, once the variation of ν_m with height has been established. The generalized Appleton–Hartree formula of Sen and Wyller[7] was used, with the aid of C-script tables computed by Burke and Hara[8].

When the integrated differential absorption is small

$$\frac{R_e}{R_0} \simeq \frac{A_e}{A_0} \qquad (2)$$

and from the measured echo amplitude ratios a measure of ν_m can be obtained. From Fig. 2 it appears that at 2.66 Mc/s this approximation is reasonable for a small range of heights near the bottom of the ionosphere. The A_e/A_0 curve of Fig. 2 was calculated from the collisional frequency curve shown in Fig. 3. These values, which are also tabulated in Table 1, have been calculated from a formula given by Phelps[9], based on laboratory measurements, and the COSPAR International Reference Atmosphere 1961 model atmosphere[10]. Also shown in Fig. 3 are values measured by Kane[11] using rocket techniques at Churchill under polar cap absorption conditions, and values measured by Schlapp[12] at Cambridge using the group retardation method. Both the results of Schlapp and Kane have been re-evaluated using the generalized Appleton–Hartree formula.

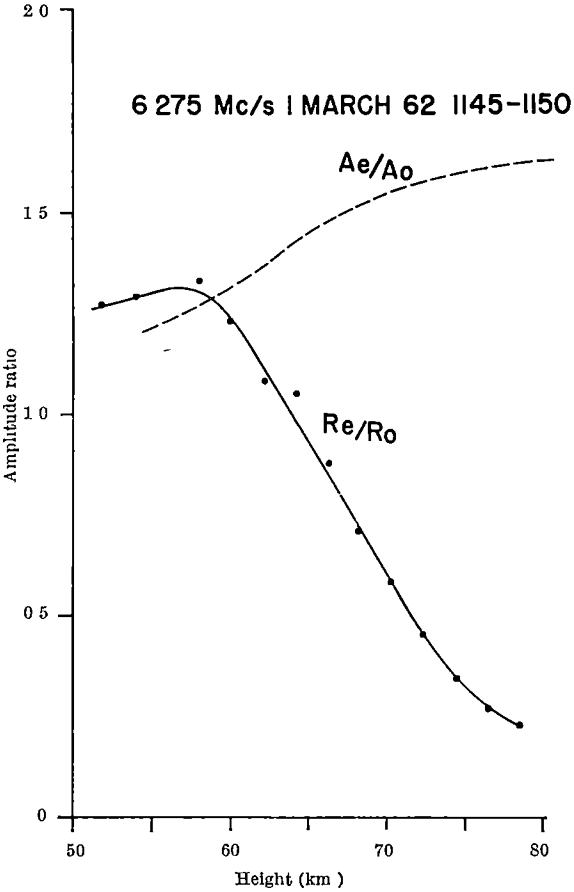

Fig. 4. Function A_e/A_0 and R_e/R_0 with height for 6 275 Mc/s for March 1, 1962 (5-min. average near the peak of a sudden ionospheric disturbance, time shown is E.S.T.)

Table 1

Height (km.)	ν_m (sec $^{-1}$)
30	9.7×10^8
40	2.3×10^8
50	6.3×10^7
60	1.8×10^7
70	4.5×10^6
80	8.4×10^5
90	1.3×10^5

The amplitude ratios obtained during the sudden ionospheric disturbance of March 1, 1962, at 6 275 Mc/s are shown in Fig. 4. Note that differential

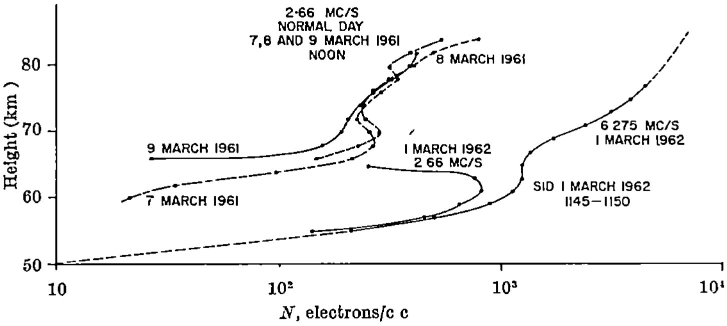

Fig. 5. $N(h)$ curves derived from observations at Ottawa at the frequencies marked. Time shown is E.S.T.

absorption appears at a height of about 57 5 km On quiet days the absorption at this frequency is negligible below about 85 km The values of R_e/R_0 at low heights are in reasonable agreement with the calculated values for A_e/A_0 In any event, the collision frequency at these heights was not greater than usual, since to bring the R_e/R_0 values into closer agreement with the A_e/A_0 values would require lower collision frequencies than shown by the curve of Fig 3 The electron densities deduced from the results of Fig 4 are shown in Fig 5, together with values deduced from 2 66 Mc /s observations for the same sudden ionospheric disturbance and for quiet days in March, 1961 Note that the data at the two frequencies are in reasonable agreement at low heights, 55–60 km , but are not above this height This is attributed to the effect of oblique reflexions at the lower frequency At the higher frequency a much more directive antenna array was used, and, moreover, there is less absorption

The absorptions that a 30 and 60 Mc /s wave would suffer in passing once vertically through the sudden ionospheric disturbance layer(s) obtained from the 6 275 Mc /s observations were computed for comparison with riometer data The calculated absorption profile at 30 Mc /s is shown in Fig 6 The $N(h)$ curve was extrapolated to higher and lower height for this purpose Neglect of these extrapolations reduces the calculated absorption at 30 Mc /s by slightly more than 0 1 db The calculated and measured absorptions are compared in Table 2

Table 2

Frequency (Mc /s)	Calculated absorption (db)	Measured absorption (db)
30	1	1 16
60	0 3	0 3

The phase and amplitude of low-frequency transmissions (80 kc) was also being recorded at Churchill from a frequency stable transmitter at Ottawa The amplitude increased by 5 db (the normal amplitude change from day-to-night amounts to about 9 db at this time of the year), and the phase lag decreased by 0 17 cycle (which is interpreted as being due to a decrease in the height of reflexion by about 2 5 km)

In conclusion, the sudden ionospheric disturbance ionization associated with the class 2^+ flare of March 1, 1962, resulted in an increase in the electron densities in the 60–75 km region by about a factor of ten,

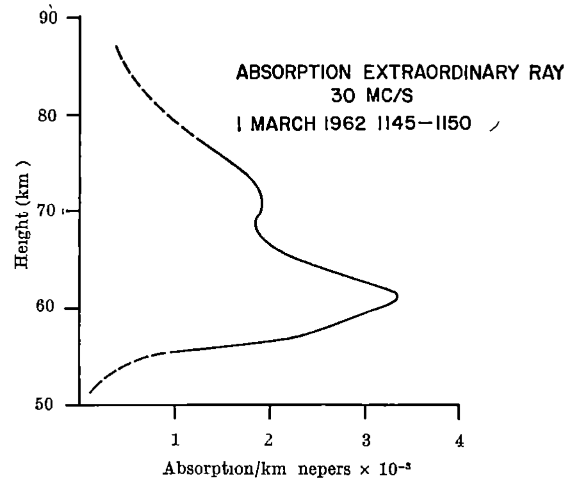

Fig 6 Absorption profile for the extraordinary ray at 30 Mc /s for the sudden ionospheric disturbance curve of Fig 5

and in a lowering of the base of the ionosphere The electron-density gradient at the base of the ionosphere, although not very accurately obtained on most quiet days, was increased over normal by about a factor of two These results are consistent with absorption changes measured by riometers, and phase and amplitude changes observed on low-frequency transmissions The change in the rate of increase of electron density with height near 60 km suggests that more than one ionization process is involved The partial reflexion observations also show that the collision frequencies at low heights during the flare are not greater than normal

FORMATION OF UNSATURATION AND CROSS-LINKS IN THE RADIOLYSIS OF *n*-ALKANES AND POLYETHYLENE

By Dr B J LYONS*

British Insulated Callender's Cables, Ltd , Research Organization, London, W 12

THERE seems little doubt that most of the organic products (including dimers and polymers) of the radiolysis of *n*-alkanes and cyclo-alkanes are formed by free radical ractions This conclusion follows from measurements of yields of free radical using chemical determination or electron paramagnetic resonance measurements[1] Moreover, Charlesby *et al* [2] have shown that the decay of anthracene in

---

* Present address Chemistry Department, Northwestern University, Evanston, Illinois

cyclo-hexane solution shows a dependence on the square root of the ionizing radiation intensity, indicating that the radical combination reaction follows bimolecular kinetics Dewhurst, however, while postulating a free mechanism for the radiolysis of the *n*-alkanes, suggests that the dimerization may actually occur as an ion-molecule reaction[3].

In accounting for the cross-linking of polymers by a free radical mechanism, allowance must be made for the observation that the radical decay-rates in these systems follow a first-order law This has been confirmed by electron paramagnetic resonance[4-6], and hydrogen exchange[7,8] studies on polyethylene and by analysis of the decay-rates of anthracene in polydimethyl siloxane[9] To explain this first-order dependence it has been suggested that radicals in polymers react with the neutral environment[9] or that they are formed in pairs, the pairs being distributed at random[4,5,7]

Pearson[10-12] has proposed a theory of cross-linking of polyethylene based solely on the reaction of unsaturated groups with radicals Dole and co-workers[13-15] have proposed an alternative mechanism based on activation of unsaturated groups through absorption of energy of excitation followed by reaction with the neutral environment to give end-linking or cross-linking Crook and Lyons[16] have suggested that unsaturated groups in polyethylene react with radicals (produced by C—H scission) through a chain mechanism (usually of very short length)

The observation of Snow and Moyer[17], that radiation-induced unsaturation in a paraffin wax (largely C_{26}–C_{27} and initially containing only small amounts of unsaturation) is more likely to be found in the cross-linked fraction, led them to postulate that, though unsaturation may be involved in cross-linking, it does not decay in the process They suggest

$$\text{—CH}_2\text{-CH}_2\text{—CH}_2\text{-CH}_2\text{—}\rightsquigarrow \text{—CH}_2\text{—CH} = \text{CH—CH}_2\text{—}$$

$$\text{—CH}_2\text{—CH} = \text{CH—CH}_2\text{—} + R \longrightarrow \text{—CH}_2\text{—CH} = \text{CH—}\dot{\text{C}}\text{H—}$$

$$\text{—CH}_2\text{—CH} = \text{CH—}\dot{\text{C}}\text{H—} + R' \longrightarrow \text{cross-linking}$$

It is the purpose of this article to show that the results of Snow and Moyer can be reconciled with the hypothesis that unsaturation decays by cross-linking if unsaturation formation and C—H scission are conceived, not as separate radiation events but as successive stages in the same radiation event

Williams[18], in suggesting that *trans*-vinylene unsaturation is formed by loss of molecular hydrogen from an alkane ion to give an olefine ion, points out that such a reaction is slightly exothermic Collinson, Dainton and Walker[19] have pointed out that a positive charge formed in the radiolysis of *n*-hexadecene-1 will probably rapidly migrate along the chain to the vinyl double bond, association with which would represent for it a more stable energy state, they suggest that such migration is followed by an ionic polymerization, and not by neutralization and radical formation It is probable that the positive charge would likewise remain associated with the trans-vinylene group in an olefine ion once it is formed from an alkyl ion A subsequent hydrogen abstraction reaction, similar to that suggested by the above workers, would lead to a loss of the unsaturated group and not its retention in the cross-linked molecules However, neutralization of such an olefine ion would release sufficient energy of excitation (approximately 10 eV) to break at least two C—H bonds and if, as seems likely, hydrogen abstraction reactions follow, thus form at least four radicals in close proximity to the unsaturated group In all probability two of these radical sites would be initially on the olefine molecule itself In a low molecular weight hydrocarbon, molecular diffusion would result in the radical decay following bimolecular kinetics, and in solid systems the absence of such diffusion would result in apparent unimolecular kinetics While intermolecular combination results in cross-linking, intramolecular migration and combination would result in the formation of additional *trans*-vinylene groups A slight post-irradiation increase in *trans*-vinylene unsaturation in a high density polyethylene has been noted by Fydelor and Pearson[12]

The foregoing mechanism would indicate that provided the unsaturation is fairly unreactive towards radical attack a higher proportion of radiation-induced unsaturation would be found in the cross-linked fraction of both low and high molecular weight hydrocarbons

The increased probability of finding positive charge, and hence of forming radicals, in the vicinity of *trans*-vinylene groups does explain the favoured nature of the *trans*-vinylene decay reaction, if this occurs through reaction with radicals A similar process may explain the marked dependence of chain fracture and cross-linking rates in polypropylene on the concentration of radiation-induced vinylidine unsaturation[20]

It is not suggested that all radicals formed by C—H scission in hydrocarbons result from neutralization of olefine ions, though the extrapolated lower limit of concentration of unsaturation in the polymer fraction of the paraffin wax studied by Snow and Moyer suggests that a high proportion of the radicals formed may arise through this process

I thank Dr R M Black for his advice and Dr L G Brazier, director of research, British Insulated Callender's Cables, Ltd , for permission to publish this article

RADIOPHYSICS

A Correlation between the Spectra of Non-thermal Radio Sources and their Brightness Temperatures

RECENT observations at nine frequencies between 38 and 3,200 Mc/s have been compiled and used to determine the spectra of 160 discrete radio sources[1] Although, in general, the spectra can be represented by a simple power law, at least for frequencies below 1,420 Mc/s, in a few cases the spectral index shows a considerable dependence on frequency

Fig 1 shows the spectra of the eleven sources which show a marked deviation from a simple power law spectrum Of these, Cygnus *A* has long been known to have a spectrum of this type[2,3]

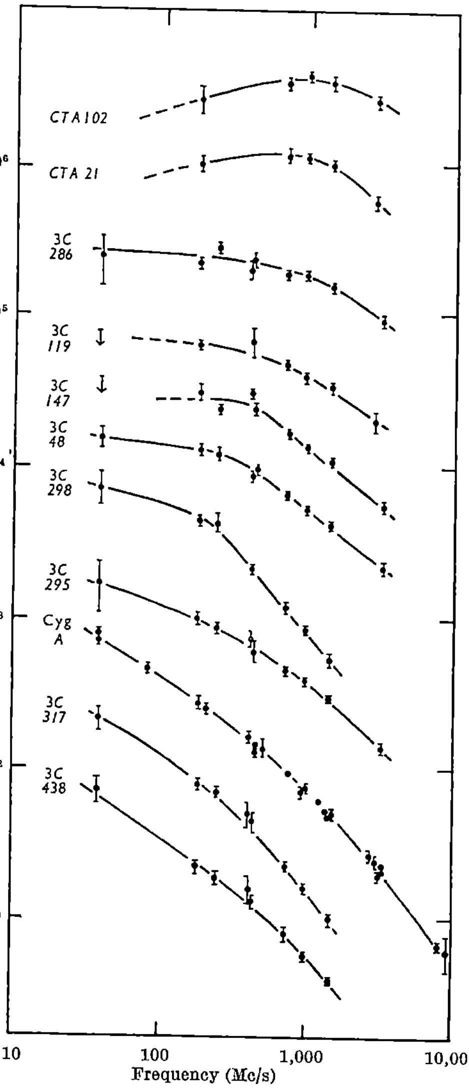

Fig 1 Spectra which have been found to show considerable curvature The sources *CTA* 21 and *CTA* 102 are taken from the list of Harris and Roberts (ref 4), while the remainder are taken from the third Cambridge catalogue (ref 5) (3*C*) The points shown for Cygnus *A* are taken from a large number of observers (ref 1)

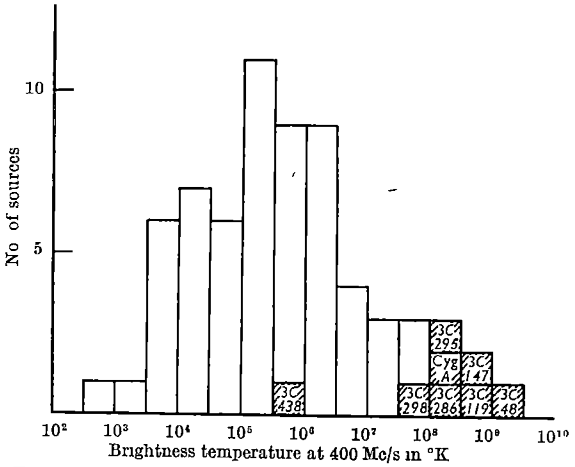

Fig 2 Histogram of the distribution of brightness temperatures Sources shown shaded have markedly curved spectra

Apart from the radio spectrum, the surface brightness is the only other intrinsic property that (apart from possible red shift corrections) can be measured without a knowledge of the distance to the source It is therefore interesting to compare these two quantities

A histogram of the distribution of apparent brightness temperatures for 66 sources is shown in Fig 2 These have been estimated from recent interferometric measurements of angular size[6-9], and include only those sources for which adequate measurements of spectra and angular size are available

On this histogram the sources with distinctly curved spectra are shown shaded (3*C* 317, *CTA* 21, and *CTA* 102, which are of this type, are not included in Fig 2 because of the lack of long spacing interferometer measurements) It is evident that there is a correlation between distinctly curved spectra and very high brightness temperatures This result is somewhat surprising in view of the fact that two of the sources with curved spectra, Cygnus *A* and 3*C* 295 (ref 10) have been identified with distant galaxies, while 3*C* 48 (ref 11) seems to be associated with an object of stellar appearance It would appear, therefore, that quite similar conditions may exist in radio sources of vastly different luminosity and linear size

It is generally accepted that radiation from non-thermal radio sources is due to synchrotron radiation The observed spectrum is then related to the energy distribution among the relativistic electrons and the mechanisms by which their energy is dissipated The observed spectrum can also be affected by a red shift in the radiation from a very distant source or by absorption along the line of sight to the source

If we assume, however, that the effects of red shift and absorption are not of primary importance, the correlation of curvature and high brightness temperature suggests that evolution within radio sources can account for the observed variety of spectra The intensity of the synchrotron radiation depends both on the energy of the relativistic electrons and on the strength of the magnetic field Thus, under conditions of minimum total energy, the existence of high surface brightness implies the presence of a strong magnetic field[12] It therefore follows that the radio spectrum of a source will become steeper with time at higher frequencies as a result of the rapid loss of energy from high-energy electrons by synchrotron emission[13] A source, therefore, with an initially flat spectrum will soon show a spectrum that is markedly curved, and will finally have a spectrum of the type observed for the majority of sources

A full discussion of such an evolutionary sequence would have to consider changes in the magnetic field and in the rate of production of relativistic electrons, and other mechanisms of energy-loss such as ionization and bremsstrahlung[14] and the physical expansion of the source

This work forms part of a joint investigation of the spectra of radio sources by the California Institute of Technology Radio Observatory, the Mullard Radio Astronomy Observatory, and the Nuffield Radio Astronomy Laboratories We thank Dr R G Conway for helpful discussions

PHYSICS

Spectra of Amine-Chloranil Complexes

SMITH[1] has shown that the spectra of some methyl substituted aniline-chloranil charge-transfer complexes contain two absorption bands not exhibited by the individual components of the complexes One of the absorption bands is an intense broad band with maximum absorption in the region of 600–800 mμ This band is thought to be the charge-transfer band of the complex The other band is an intense band with a well-defined maximum in the region of 320–380 mμ McGlynn[2] has interpreted this band as being a charge-transfer band of the complex also and has suggested that methyl-substituted aromatic molecules have two similar ionization potentials which give rise to two charge-transfer bands Evans[3] has shown that the spectrum of oxygen-perturbed dimethylaniline has a shoulder with maximum absorption at 380 mμ. He has interpreted this shoulder as being due to the superposition of two charge-transfer bands corresponding to the two ionization potentials of the methyl-substituted aromatic molecule suggested by McGlynn

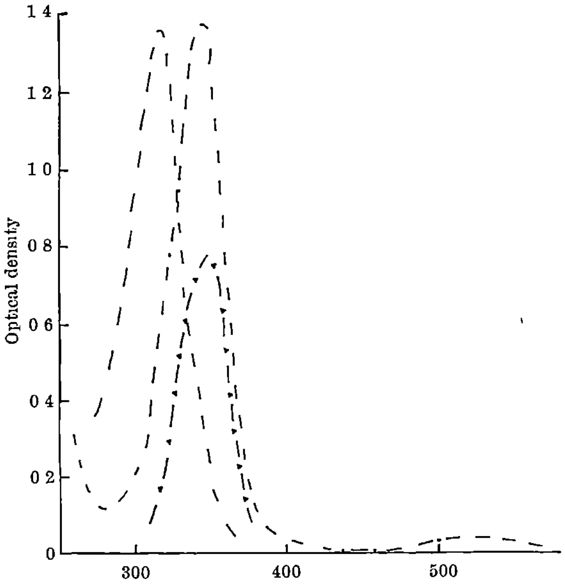

Fig 1 Absorption spectra of chloranil in *a*, triethylamine (— — —), *b*, 50 per cent aqueous diethylamine (– ▲ —), *c*, (5 *M*) ethylamine in 50 per cent aqueous ethanol (—●—)

I[4] have shown that the spectrum of oxygen-perturbed tryptophan has a shoulder with maximum absorption at 380 mμ This shoulder has been inter-

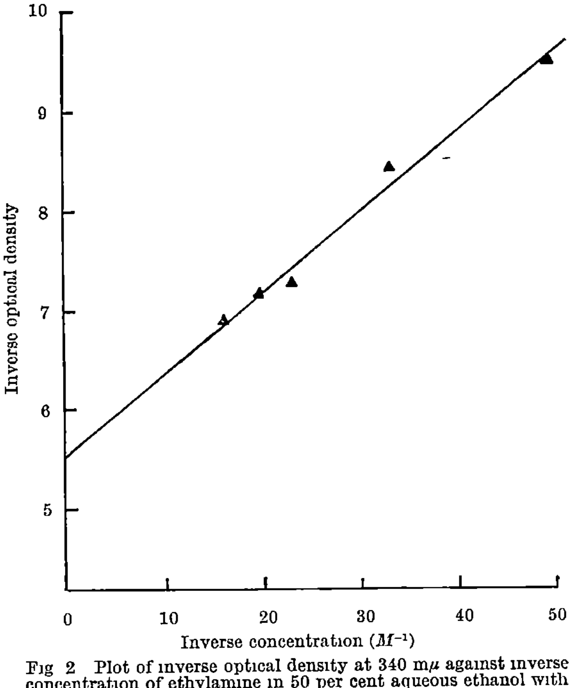

Fig 2 Plot of inverse optical density at 340 mμ against inverse concentration of ethylamine in 50 per cent aqueous ethanol with constant concentration (2×10^{-5} *M*) of chloranil

preted as being due to the ground-state to first triplet state transition of tryptophan

The spectra of some aliphatic amine-chloranil mixtures have been investigated These are shown in Fig 1 It is seen that the ultra-violet absorption band of chloranil in aliphatic amines is shifted to longer wave-length as compared with its position in inert solvents such as n-heptane and ethanol, etc [5], where the peak of the chloranil absorption band occurs at about 285 mμ No strong absorption bands are observed in the visible region such as occur in the aromatic amine-chloranil complexes[1] The faint band observed at 540 mμ is similar to that displayed by old solutions of chloranil in ethanol and is probably due to a small amount of chloranilic acid formed from chloranil in the presence of ethanol

A study has been made of chloranil–ethylamine mixtures in 50 per cent aqueous ethanol The optical absorption of the chloranil-ethylamine mixtures was found to be reversible and to obey the Benesi–Hildebrand equation for 1 1 complexes[6] A plot of the inverse optical density at 340 mμ against the inverse concentration of ethylamine with a constant concentration of chloranil $(2 \times 10^{-5} M)$ is shown in Fig 2 The equilibrium constant of the complex derived from this plot is 7 5 l /mole at 20° C

The position of the peak in the chloranil-ethylamine spectra is quite independent of concentration The aliphatic amines do appear to form 1 1 charge-transfer complexes with chloranil These charge-transfer complexes must be of the n–π type, charge-transfer occurring from the lone-pair electrons of the nitrogen in the amino-group

It appears that the intense absorption band, in the region of 320–380 mμ, observed in the spectra of the methyl substituted aromatic amine-chloranil complexes is due to the amino part of the molecule and not to the aromatic system as suggested by McGlynn[2] Tsubomura[7], on considering the structure of dimethylaniline, has suggested that dimethylaniline acts as an n-donor rather than a π-donor and should therefore behave more like an aliphatic amine than a methylated benzene in forming charge-transfer complexes One feature of n–π complexing is the shifting of the ultra-violet absorption bands of the acceptor molecule on complexing[8] The intense band in the region of 315–380 mμ in the spectra of the amine-chloranil complexes does not resemble the charge-transfer bands normally observed with chloranil complexes[1] but is very similar to the original chloranil band Thus in ethanol, chloranil has a maximum absorption at 290 mμ (34,500 cm^{-1}) and a minimum at 245 mμ (40,800 cm^{-1}) The absorption in the ethylamine-chloranil complex is a maximum at 350 mμ (28,600 cm^{-1}) and a minimum at 285 mμ (35,200 cm^{-1}) The differences between the two maxima and the two minima are 5,600 cm^{-1} and 5,900 cm^{-1} respectively It can be concluded that the intense band in the region of 315 mμ–380 mμ observed in the spectra of amine-chloranil complexes is the absorption band of chloranil shifted to longer wave-length on complexing and is not a charge-transfer band

Evans's explanation of the oxygen-dimethylaniline spectrum thus appears to be incorrect The shoulder observed at 380 mμ (3 26 eV) in the dimethylaniline-oxygen spectrum[3] could well be the first singlet–triplet transition of the dimethylaniline The first singlet state of dimethylaniline is at 4 25 eV [9] This gives a singlet–triplet energy separation of 1 eV This is comparable with the singlet–triplet energy separations of the polycyclic aromatic hydrocarbons[10]

Effects of Nuclear Radiation on Electrical Conductivity of Chromic Oxide

EXPERIMENTS performed in the past few years on nuclear radiation effects on oxidic semiconductors[1-5] have shown that their electrical conductivity is strongly influenced by irradiation The results so far reported refer mainly to oxidic semiconductors with relatively large initial charge carrier concentration In order to obtain further information about radiation effects on oxidic semiconductors with small initial charge carrier concentration, we chose for our experiments pure chromic oxide (Cr_2O_3), known as a p-type semiconductor with small hole concentration at ordinary temperatures

For measurements, compacts were prepared by compressing Cr_2O_3 powder (A R grade, 'Chinoin'), at 2,000 kgm /cm^2, into cylinders (8 mm diameter, 8 mm height) and sintering for 10 hr in air at 1,150° C Irradiations of the samples (inserted in quartz ampoules) were performed in an experimental hole of the 2 *MW* enriched uranium reactor at this Institute

The following electrical measurements were made

(*a*) Temperature-dependence of the electrical conductivity of the samples in the range 350°–950° K , before and after exposure in the reactor to an integrated fast neutron flux of $\sim 4 \times 10^{17}$ neutrons/cm^2

(b) Time-dependence of electrical conductivity of the samples during in-pile exposure up to an integrated fast neutron flux of $\sim 2 \times 10^{17}$ neutrons/cm^2

In Fig 1 log σ versus $10^3/T$ is plotted for a sample of chromic oxide before (curve 1) and after (curve 2) exposure in the reactor to a fast neutron dose of $\sim 4 \times 10^{17}$ neutrons/cm^2 It is seen that the conductivity is much smaller after irradiation, but up to 700° K (below which the temperature-dependence of σ is reversible) the activation energy is very little affected by irradiation The fact that exposure in the reactor does not change the activation energy, while the conductivity drops drastically, shows that irradiation produces mainly hole-traps which lead to a decrease in the hold concentration but does not affect its temperature dependence (in the range considered)

By heating the irradiated sample to higher temperatures (above 700° K) its conductivity tends more and more toward the values it had before irradiation (Fig 1) and, at about 800° K , curve 2 overlaps with curve 1 When the sample is now cooled, the value and the temperature-dependence of its conductivity are the same as before exposure to radiation It may be concluded that at temperatures above 700° K

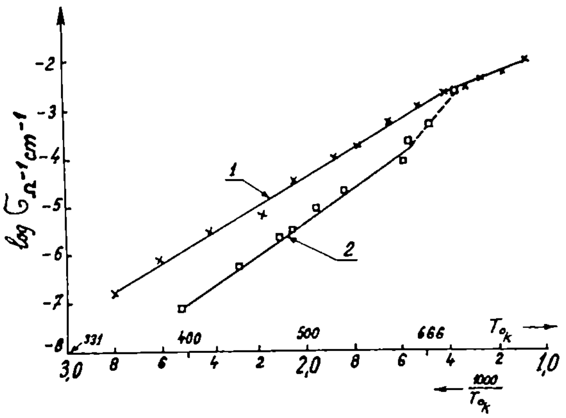

Fig 1 Temperature-dependence of electrical conductivity of chromic oxide before (curve 1) and after (curve 2) irradiation in an integrated fast neutron flux of ~ 4 × 10^{17} neutrons/cm^2

a fast annealing of the defects occurs and the electrical conductivity of the sample returns to the values before irradiation

To determine how the conductivity of chromic oxide varies with the fast neutron dose, the time and consequently the irradiation dose-dependence of the electrical conductivity of a chromic oxide sample was recorded during exposure in the pile (Fig 2) The temperature of the sample being irradiated was always kept at 343° K, so that all conductivity values (including those in absence of the radiation field) were given for this temperature

From Fig 2 it is seen that introducing the sample in the reactor is accompanied by a quick rise in conductivity, however, when the chain-reaction is suddenly stopped, the intensity of ionizing radiation decreases very rapidly and the conductivity decreases as well This shows that the initial rise in conductivity is due to ionization caused by reactor radiations After this initial rise the conductivity soon reaches a maximum, and a subsequent decrease, due to lattice displacements under fast neutron irradiation, occurs

The initial portion of the curve is a straight line, but at higher doses there seems to be a saturation effect As we have seen, these defects are permanent at temperatures below 700° K, so that after irradiation the conductivity of the sample will have a much lower value than before

The following conclusions may be drawn from these results

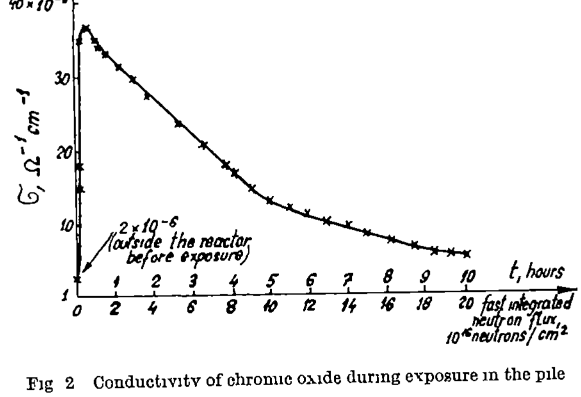

Fig 2 Conductivity of chromic oxide during exposure in the pile

(a) Nuclear radiations cause two kinds of effects in chromic oxide which manifest themselves in changes in its electrical conductivity (1) Ionization effects, which lead to a rise in the conductivity due to the generation of charge carriers in excess, these effects are not permanent, they disappear after cessation of radiation (2) Displacement effects which lead to a decrease of the conductivity due to formation of trapping centres in the chromic oxide lattice, these effects are permanent at room temperature but can be annealed at higher temperatures (b) Below annealing temperature, the temperature-dependence of the electrical conductivity of chromic oxide is not affected by irradiation

CHEMICAL ENGINEERING

Anomalous Excitation Processes in Flames and Detonations

SPECTROSCOPIC study of flames, particularly those of hydrocarbons, has revealed abnormally strong emission from their reaction zones[1] The radicals produced during the combustion process itself such as OH, CH and C_2 all show the effect and so do the non-resonance lines of added impurities such as iron and lead Excitation energies up to 173 kcal /mol have been observed but the processes responsible have remained obscure

In order to examine the combustion process in more detail I have used a brightness and emissivity method[2] to measure the electronic temperature in detonation waves Equimolar oxy-acetylene, sometimes with a trace of cyanogen, and oxy-cyanogen have been used as fuels These basic mixtures were further diluted with hydrogen, carbon monoxide, argon, or nitrogen Both the C_2 and CN radicals have been investigated

To simplify the analyses, the detonation waves were all initiated by a shock wave from a bursting diaphragm and overdriven The initial pressures were in general below 1 cm mercury and the diaphragm was burst with about 8 atm of hydrogen The detonations were carried out in a 'Pyrex' tube of 2 in diameter and 5 ft long With a sufficiently long driver section the pressure behind the detonation front will be constant

The temperature-histories obtained all showed a high value at the front which relaxed to a constant value a little behind the front A typical record is shown in Fig 1 Only in detonations through oxy-cyanogen initially at pressures greater than 1 cm mercury was this temperature spike not observed

The value obtained for the temperature in the plateau agreed very well with that calculated allowing for chemical and thermodynamic equilibrium

When hydrogen was present it appeared in the equilibrium gases partly dissociated together with carbon monoxide and/or nitrogen and argon as the

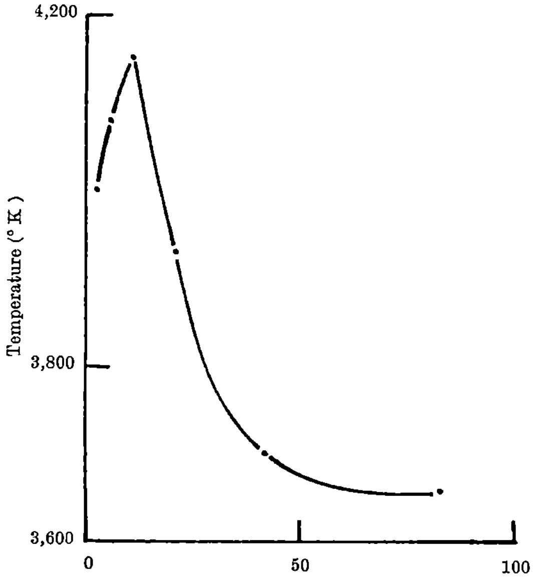

Fig. 1. Temperature measured in CN violet (0,0) band in a $C_2N_2 + O_2 + H_2$ detonation. Initial pressure 9 mm mercury, final pressure 540 mm mercury. Driver pressure 8.2 atm hydrogen. Shock speed, 2.58 mm/μs.

case might be. It was at first considered that the falling temperature was caused by the dissociation of the hydrogen, but the presence of the spike in cyanogen–air and oxy-cyanogen plus carbon monoxide showed that it was not necessarily associated with the hydrogen.

The duration of the spike was measured from the records and used to derive (1) the vibrational relaxation time of carbon monoxide as a function of the equilibrium temperature, (2) the rate constants for the dissociation reactions $M + H_2 \rightarrow M + 2H$ where M can be H_2, N_2, CO, H or A.

The relaxation times of the spike were found to correlate very well with the carbon monoxide times given by Windsor, Davidson and Taylor[3] but gave scattered rate constants for hydrogen rather lower than those of Rink[4].

These results clearly indicate that vibrationally excited carbon monoxide is among the products of the combustion of both acetylene and cyanogen. There are a number of possible reactions capable of producing this activated carbon monoxide.

The vibrational relaxation time of carbon monoxide is very long, and so it is quite likely that it can act as a carrier of excess energy. It is becoming clear that vibrational-electronic energy exchanges are important routes to the production of excited species in hot gases[5] and so the vibrationally excited carbon monoxide may be responsible for the anomalous effects observed in the combustion of hydrocarbons.

CHEMISTRY

Chromatographic Identification of Complex Mixtures of High-Boiling Compounds

GAS-LIQUID chromatography[1] is a commonly accepted method for the identification of substances in their mixtures. For these purposes a comparison of retention data on non-polar and selected-polar stationary phases is used with advantage.

By applying this method on a mixture of substances we have to admit that in the chromatogram transference and overlapping of components occur. Without chemical simplification of the mixture, the chromatogram is difficult to read. Further, by applying high temperatures for identification of the high-boiling compounds the choice of polar stationary phases, as well as their selective effect, decrease considerably.

In the case of complex mixtures such as coal tar fractions or substances of natural origin we mostly encounter overlapping of gas-liquid chromatography peaks, which makes identification sometimes impossible. In connexion with these facts, the amount of information about the composition[2] of the mentioned materials decreases with their increasing boiling points. This disadvantage has been overcome by a new method in which the high-separating performance of gas-liquid chromatography is connected with the high polarity of solid adsorbents, when thin-layer chromatography is used. The scheme can be demonstrated by the following example.

About 10 mgm. of anthracene oil from coal tar is separated in a high-temperature chromatograph with katharometer on the non-polar stationary phase ('Apiezon *L*') at a temperature of 250°–270° C. The anthracene–phenanthrene peak to be examined is trapped in a capillary ice-cooled U-tube. The trapped mixture is dissolved in 1 or 2 drops of warm benzene and the solution applied in the usual way[3] on a plate coated with free silica gel (grain size 0.03–0.08 mm., thickness 0.5 mm.). The chromatogram is developed by means of *n*-hexane/benzene mixture (1:1 vol.) and after evaporation of the solvent the plate is inspected under ultra-violet light. According to the situation of the luminescent spots the areas on the plate containing the separated substances are marked. Silica gel from the marked areas is transferred into the capillary tube with a small glass wool tampon using an exhausted air stream. From the column of adsorbent detained in the capillary tube the substance is displaced by several 0.1 ml. methanol or pyridine. The substance might be contained in the first 2–3 drops of solvent which break through the column. A part of this solution is generally used directly for the injection into the chromatograph with an ionization detector. It serves for quantitative analysis or for the further examination on the same or different stationary phase. In this way, without any other preparation, it is possible to separate and detect components up to 0.1 per cent weight in the original mixture. In the peak of anthracene and phenanthrene examined the impurities of carbazole and acridine were easily estimated. Retention ratios are shown in Table 1.

I would like to point out that the adsorbent polarity is higher than any of the polar stationary phases used in gas-liquid chromatograhy[4]. Therefore the separation runs in groups according to the type of the function groups. This means that in, or near, the zone of the first member of the series even

Table 1. Relative Retention Characteristics

Compound	Gas-liquid chromatography 'Apiezon L', 260° C.	Thin-layer chromatography, silica gel/n-hexane/benzene, 1 : 1 v. (R_F)	Type of function group
Anthracene	1·00	0·88	hydrocarbon
Carbazole	1·02	0·55	—NH—
Acridine	1·01	0·06	—N=
6-Methyl quinoline	0·15	0·07	—N=
5-Methyl indole	0·23	0·52	—NH—
Fluorene	0·49	0·93	hydrocarbon
1-Methyl anthracene	1·50	0·89	hydrocarbon
1-Methyl acridine	1·52	0·06	—N=
Benzcarbazole	>10	0·58	—NH—

its homologues can be found. This method can be successfully used for separation and identification not only of alkyl homologues of anthracene, phenanthrene, carbazole or acridine, but also other types of structurally similar substances as, for example, benzcarbazole and other condensed heterocyclic compounds.

This method has proved to be commonly applicable for identification of mixtures of high-boiling substances. The method can be further developed by using other adsorbents, which have not been known in thin-layer chromatography up to now (see ref. 3), for example, Linde molecular sieves, substituted montmorillonites ('Bentone 34 and 38', by Abbey Chemicals, Ltd., London), modified silica gels, etc. Interesting results can be achieved by applying development solvents, which cannot enter the pores of the molecular sieves.

Acrylamide Gel as an Electrophoresis Medium

The use of acrylamide gel as a supporting medium for electrophoretic separation was forecast by Ornstein[1] and by Raymond and Weintraub[2], and was rendered feasible by the work of Dr. S. Raymond[3] of the William Pepper Laboratory, University of Pennsylvania, with Wang[4], Nakamichi[5], and Nakamichi, Brodsky and Bryant[6]. At present, the procedure is as follows. 'Cyanogum 41$^{(R)}$' monomer mixture, 5 per cent dissolved in *tris*-ethylenediamine tetracetic acid-borate buffer[4] is mixed with 0·2 per cent catalyst as described by Raymond and Wang[4] and poured into a special electrophoresis cell (Fig. 1) which was devised by Raymond and is to be described in detail elsewhere[3]. However, the *E–C* Apparatus Corporation of Swarthmore, Pennsylvania, has recently marketed the apparatus and materials for the application of this technique, which this corporation calls 'vertical gel electrophoresis'.

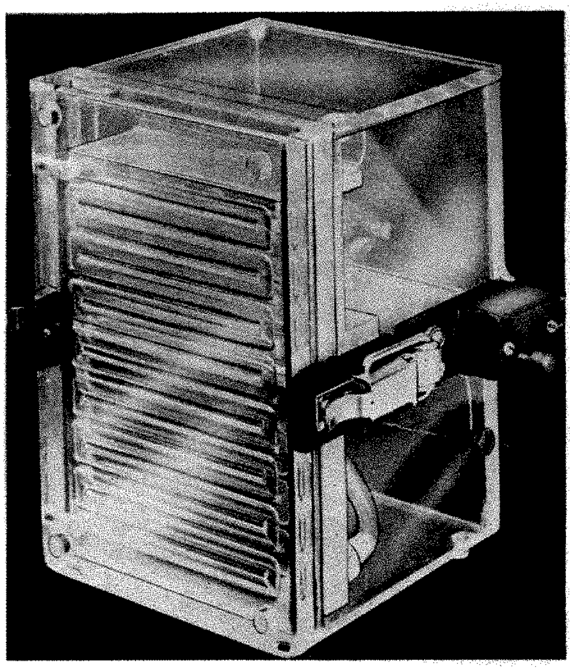

Fig. 1. Vertical gel electrophoresis cell, showing upper and lower electrode chambers; cooling water channels embedded in the walls of the gel compartment, electrical connector, and clamps holding the two parts of the cell together

After polymerization of the gel is complete the apparatus is placed in a vertical position and both electrode chambers are filled with a buffer solution. The sample in appropriate buffer solution (unbuffered serum can be used directly) is layered into premoulded slots in the top edge of the gel and subjected to electrophoresis. For usual types of protein at alkaline pH the lower electrode is the anode and the upper one is the cathode. A current of 100–150 m.amp. is applied (300–400 V.) for 2 hr. to obtain migration of albumin 10 cm. downward through the gel. During electrophoresis, cooling water is circulated through the plates adjacent to the gel slab for temperature control. After electrophoresis the gel is stained 30 min. with amido black and destained in 10 per cent acetic acid solution.

Because of absence of electrosmosis in acrylamide gel medium, all serum proteins, including γ-globulin,

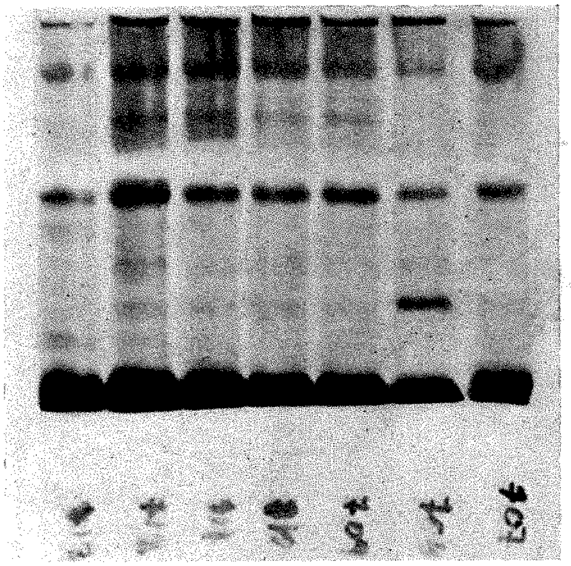

Fig. 2. Serum protein electrophoretic patterns of a series of seven random samples after simultaneous electrophoretic resolution in the vertical gel apparatus of Fig. 1; gel concentration 5 per cent, buffer *tris*-EDTA pH 9·2, field strength 15 V./m., duration 2 hr., stained with amido black

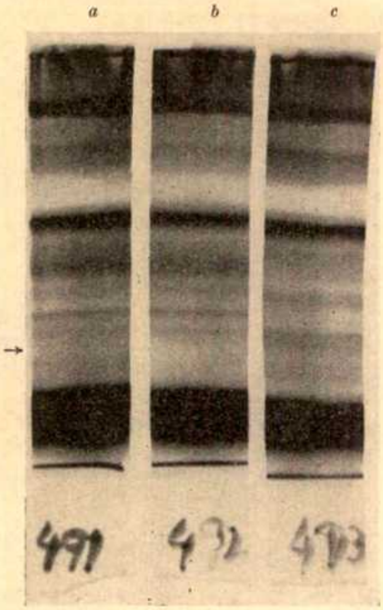

Fig. 3. Serum protein patterns on 5 per cent gel; 491 and 493 are native sera; 492 was a portion of 491 heated at 56° for 30 min. before electrophoresis. A component just behind the broad albumin band in *a* and *c* shows more clearly on the original gel than in the photograph

move from the point of application toward the anode. During the initial period of the electrophoresis, the proteins in the sample migrate downward through the free solution to form a thin, concentrated layer at the surface of the gel, which then enters the gel as a thin, sharply defined zone. The resulting patterns, Fig. 2, show much improved resolution of serum proteins as compared with usual techniques. Hæmoglobins are also well resolved in this technique.

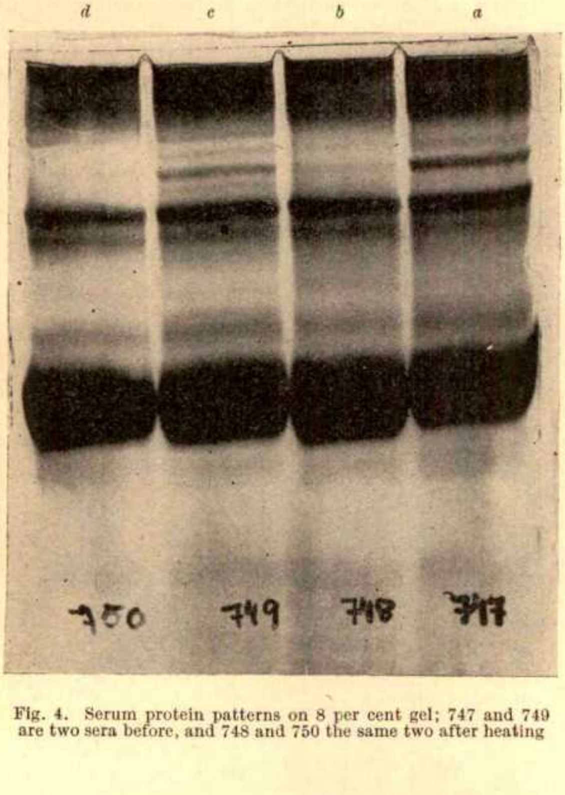

Fig. 4. Serum protein patterns on 8 per cent gel; 747 and 749 are two sera before, and 748 and 750 the same two after heating

The technique described has advantages over the technique described by Chang[7]. Several protein samples (4–12 in the apparatus described) can be intercompared directly on a single gel slab under identical conditions of gel polymerization, temperature, buffer composition, field strength, and duration of electrophoresis. Larger protein samples, for example, 2 ml. of 10 per cent protein solution, can be applied for semi-micro preparative electrophoresis; individual bands can be eluted from the gel by extraction with buffer or by electrophoresis. The apparatus has also been applied effectively to studies of gel structure in relation to electrophoresis effects.

As an example of the latter, Figs. 3 and 4 demonstrate the effect of gel concentration on the resolution of serum components. Fig. 3 *a* and *c* shows two individual sera resolved on a 5 per cent 'Cyanogum' gel, *b* being the same serum sample as *a*, incubated at 56° C. for 30 min. before subjecting it to electrophoresis. The disappearance of the component indicated by the arrow is typical of all serum samples studied in this procedure. Fig. 4 similarly shows two individual sera subjected to electrophoretic resolution in 8 per cent gel before (*a* and *c*) and after (*b* and *d*) heating. At this gel concentration the pattern is qualitatively different. The component just behind albumin does not disappear on heating, but instead, a new system of bands, which have appeared between the origin and the β-band now, are those which disappear after incubation.

We believe that the effect of gel concentration is related to the pore size of the gel, of which a theoretical analysis is in preparation.

Solution Hydrates of Aqueous Non-electrolytes

FRANKS and Johnson[1] recently developed a computer method for the accurate determination of partial molar quantities from the measured total properties of binary systems. In their treatment of the volume of aqueous ethyl alcohol solutions, an unexpectedly complex and apparently anomalous variation of the ethyl alcohol partial molar volume was revealed at 0·06 alcohol mole fraction over the temperature-range 0°–30° C. In addition to the known[2] increase of the water solvent partial molar volume and the decrease of the alcohol partial molar volume to a minimum at about 0·08 alcohol mole fraction, the alcohol partial molar volume–concentration contour furnished[1] a hitherto unobserved change in course at 0 06 alcohol mole fraction appearing as a shoulder at 10° C which progressively developed with increasing temperature to furnish a small but definite peak at 30° C.

Elsewhere[3], the increase of the solvent water partial molar volume has been interpreted as arising from the orientation of hydration shell water adjacent to the ethyl group of the alcohol It is now proposed that the alcohol partial molar volume anomaly at 0 06 alcohol mole fraction derives directly from, and provides direct evidence for, the existence of a three-dimensionally hydrogen-bonded liquid hydrate of composition C_2H_5OH 17H_2O Such a liquid hydrate would involve 28-fold co-ordination of the alcohol molecule by water with the alcoholic-OH group hydrogen-bonded to the water cage, the solution structure being likened in respect to short-range order to a broken-down structure II gas-hydrate[4] of formula M 17H_2O

This interpretation provides a direct structural basis of the older hydrate theory of aqueous solution as developed by Pickering[5] in 1893, provided that the aqueous solutes are limited to non-electrolytes and that the meaning of a molecule of hydrate in solution is understood in the general crystallographic sense as the composition of the solution repeat unit, bearing in mind that the solution repeat unit composition does not define the hydration number of the solute but is structurally and geometrically related to it The solid gas hydrates[4] of dimethyl ether, ethylene oxide and of acetone, lead one to expect that the molar volume anomaly presented by aqueous ethyl alcohol will not be limited to ethyl alcohol alone, but will be generally exhibited in dilute aqueous solutions of many of the smaller, soluble, organic non-electrolytes

Fluorescence of Quinine in an Alkaline Medium and in Absolute Ethanol

PAPERS dealing with fluorescence of quinine only give the characteristics of this compound in an acid medium[1-4] Some publications suggest that quinine does not fluoresce at all in an alkaline medium[5,6]

In our experiments with quinine we discovered some fluorescent characteristics of quinine in an alkaline medium and in absolute ethanol which so far as we know have not been mentioned previously (Table 1) The maxima in an acid medium are given for comparison The ratio of intensity of the fluorescence in the media mentioned is approximately 1 10 60 for alkali, alcohol and acid respectively

Table 1 EXCITATION AND FLUORESCENCE MAXIMA OF QUININE (2 μg/ml) IN DIFFERENT MEDIA
Figures between brackets indicate that there is no distinct maximum but only a shoulder

Medium	Excitation maxima (mμ) as recorded	Fluorescence maximum (mμ) as recorded
0 1 N sulphuric acid	250, [310–320], 350	442
Absolute ethanol	[230–250], [280–290], 327	350
0 01 N sodium hydroxide	[230–250], [280–290], 327	365

Table 2 ABSORPTION OF QUININE (10 μg/ml) IN DIFFERENT MEDIA THE OPTICAL DENSITY IS GIVEN BETWEEN BRACKETS

Medium	Wave-lengths of maximum absorption (mμ)
0 1 N sulphuric acid	250 [0 900], 316 [0 125], 348 [0 165]
Absolute ethanol	234 [0 860], 280 [0 125], 319 [0 145], 333 [0 160]
0 01 N sodium hydroxide	231 [0 940], 282 [0 115], 327 [0 145]

We used a Farrand spectrophotofluorometer equipped with a 1P28 photomultiplier tube, a pen-and-ink recorder (Micrograph from Kipp, Delft) and a 10 × 20 × 50 mm Farrand quartz cuvette The entrance slits were 2 mm, the exit slits 0 5 mm for both monochromators

The differences in excitation maxima might be due to artefacts, however, the ultra-violet absorption spectra of quinine (10 μg/ml) in the foregoing media showed that the wave-lengths of maximum absorption (Table 2) were in good agreement with the excitation maxima in Table 1 Such an agreement between excitation and absorption maxima has already been demonstrated for quinine in an acid medium[3]

The fact that the fluorescent characteristics of quinine in different media are quite distinct may be used for a better identification of this compound in qualitative analysis

Influence of Deoxyribonucleic Acid on the Intermolecular Structure of Water

SEVERAL years ago Jacobson[1] directed attention to the fact that the helical structure of deoxyribonucleic acid (DNA) proposed by Watson and Crick[2] showed a remarkable relationship to the intermolecular structure of liquid water, which has been postulated to be quasi-crystalline and only slightly different from ice[3] Jacobson proposed that when DNA is dissolved in water, an increased ordering of the water structure results and further suggested this increased ordering of the intermolecular water structure accounts for the high viscosity and dielectric constant of DNA solutions In later work Jacobson *et al* [4] studied the proton resonance spectra of DNA solutions and interpreted the results of their experiments as offering further support of the above-mentioned proposals Jacobson[5] then made a detailed study of the dielectric constants of DNA solutions and interpreted the results as further evidence of stabilization of the normal water structure by the formation of hydration shells with diameters at least one-quarter the length of the dissolved macromolecules, he also cited certain X-ray studies[6] for further support of his hypothesis The sodium salt of deoxyribonucleic acid (sodium thymonucleate) was used in all Jacobson's experimental work

The work recorded here was undertaken with the view of obtaining infra-red data on the nature of the stabilized lattice structure reported by Jacobson In their early work on structure of water, Bernal and Fowler[7] suggested that the extent of the liquid water structure was greatest at low temperatures and decreased as the boiling point was approached, later work[3] on the quasi-crystalline nature of water has differed in details from the original Bernal–Fowler work but has not altered their general view that the intermolecular structure is most extensive at low temperatures Bernal and Fowler also discussed the influence of ionic solutes on the intermolecular structure of water

The infra-red spectrum of water was investigated by Ganz[8], who found shifts in the positions of major bands as the water temperature was raised from 17° C to 84° C Williams *et al* [9] examined the effects of various ionic solutes on the water spectrum, their results indicated that, in general, large ions have effects similar to those produced by increasing the water temperature as predicted by Bernal and Fowler, whereas small ions, notably F^-, have the reverse effect Hence, if DNA has the influence proposed by Jacobson, the solvent portion of the infra-red spectrum of a DNA solution at room temperature would correspond to that of pure water at a lower temperature

Although most of the characteristic water bands are overlapped by characteristic bands in the spectrum of DNA itself, the 'associational' water band at 4 7μ is in a spectral region not overlapped by characteristic DNA bands Ganz's work[8] had shown that this band shifts to shorter wave-lengths and becomes more intense as the temperature is reduced, thus, if Jacobson's hypothesis is valid, the 4 7μ band would be expected to shift to shorter wave-lengths when DNA is dissolved in water

In the course of the present work, the 4 7μ water band was examined in pure water and in a series of solutions of DNA varying in concentration from 6 per cent by weight to highly concentrated gels A Perkin-Elmer 21 spectrograph with a lithium fluoride prism was used, the absorption cells were fitted with calcium fluoride windows The DNA material used was sodium deoxyribonucleate prepared from calf thymus One set of solutions was prepared from DNA material with an intrinsic viscosity of 0 064 dl/g and molecular weight of the order of 10^5, which was supplied by the Light Company, another set of solutions was prepared from material having an intrinsic viscosity of 11 4 dl/g and molecular weight of approximately 3×10^6, which was prepared by Worthington Although, on the basis of Jacobson's claims, even more dilute DNA solutions would have been expected to produce marked shifts of the 4 7μ band, no shifts were observed in any of the solutions In order to check the present instrumentation, some of the earlier work on solutions of electrolytes was repeated with positive results in agreement with those obtained earlier If extensive intermolecular ordering of the type proposed by Jacobson had existed, the resulting shift of the water band could easily have been observed Thus, on the basis of the present infra-red work, it may be concluded that any influence DNA may have on the structure of water is quite different from those produced by temperature variations and by strongly ionized solutes

In view of the negative results afforded by the infra-red investigations, it was decided that, owing to the improved techniques now available, it might be well to check the early nuclear magnetic resonance data reported by Jacobson. The present nuclear magnetic resonance experiments were performed by Dr J Smidt at the Central Laboratory of the Staatsmijnen (The Netherlands) on numerous samples supplied from our laboratory and prepared from the highly polymerized DNA described above, the measurements were made at 40 Mc/sec in a highly homogeneous magnetic field, the percentage by weight of solutions and gels, both in pure water and in 0 05 N sodium chloride, ranged from 0 3 to 19 per cent

On the basis of the early work[4], which used photographic recording of oscilloscope traces, marked broadening of the proton line would have been expected even at lower concentrations than those utilized in the present experiments However, no broadening of the water resonance peak, which could not be accounted for by ordinary viscosity effects, has been noted in the present set of measurements, the results of which are summarized in Table 1, for the sake of comparison, we have also tabulated the figures observed for solutions of simple salts It is seen that as regards line widths the ionic solutes give an effect parallel to that observed in infra-red, that is, large ions raise the structure temperature thus leading to a narrower line, whereas small ions decrease this temperature giving the converse result[10]

Table 1 OBSERVED PROTON LINE WIDTH IN AQUEOUS SOLUTIONS

Solutions	Percentage by weight	Line-width (mG)
DNA in pure water	0 5	1 3
	1 5	1 5
	19 0	4 8
DNA in 0 05 N sodium chloride	0 3	1 4
	1 9	1 5
	16 8	5 0
Sodium chloride	0 05 N	1 2
Sodium fluoride	Saturated	1 4
Potassium iodide	Saturated	1 0

It seems thus well possible that there may have been some unrecognized instrumental difficulties involved in the earlier investigations A parallel study of the dielectric behaviour of water adsorbed on DNA materials and proteins is now in progress and a full account of this will be given elsewhere

In view of the negative infra-red results obtained in the present work, together with the lack of agreement between the present nuclear magnetic resonance results and the early experimental results of Jacobson, grave doubt must be raised as to the validity of Jacobson's quite attractive hypothesis regarding the influence of DNA on the water structure

We thank Prof J Duchesne for directing our attention to this problem

Esterification of Fatty Acids with Glycerol

Biswas and Ganguly[1] have recently published observations on the esterification of fatty acids with glycerol which are not in full agreement with the results of the work carried out at present in this Laboratory It is hoped to publish the details of this work elsewhere, but it might be of interest to discuss a few salient points here

Biswas and Ganguly state that since esterification of fatty acids with glycerol and glycerolysis of fats yield appreciable amounts of β-monoglycerides the ignoring of their presence could lead to a wrong computation of diglycerides and hence also of triglycerides based on the estimation of monoglycerides and hydroxyl values (Incidentally the results for β-monoglyceride contents obtained by Biswas and Ganguly in the esterification of oleic acid, namely, 0 04 per cent, differ greatly from the value of 3 per cent obtained under similar conditions in this Laboratory, and are probably much too low) The occurrence of β-monoesters in technical monoglycerides prepared by alkali-catalysed glycerolysis of fats has been repeatedly reported in the past few years[2–4] and Biswas and Ganguly's advice as to the need of accounting for their presence appears reasonable However, there is here a curious anomaly Some years ago Feuge and Bailey[5] suggested that glycerolysis proceeds according to chance inasmuch as the amounts of mono-, di- and tri-glycerides found experimentally in equilibrated products follow closely compositions calculated on the basis of random distribution of acyl groups These results were confirmed recently by Choudhury[6] in a number of oils In his investigation the conclusions were based on the estimation of α-monoglycerides by the periodate method and on hydroxyl values, the presence of β-monoglycerides being dismissed as insignificant In reality β-monoesters in freshly prepared products may amount to as much as 10 per cent of total monoglycerides and normally to about 3 per cent absolute Since on the basis of hydroxyl values 1 per cent of monoglyceride with an average hydroxyl value of 320 is equivalent to 3 5 per cent of diglyceride with an average hydroxyl value of 90 it would follow that Choudhury's conclusions regarding glycerolysis were wrong If in his calculations the hydroxyl values due to β-monoglycerides were taken into consideration, the contents of diglycerides would, in most cases, be reduced by some 10 per cent and the contents of triglycerides increased by a similar amount The results would be incompatible with random esterification

However, recent investigations[4,7] in which total mono- di- and tri-glycerides were determined chromatographically point clearly towards random or near random esterification It would seem therefore justifiable to suggest that Choudhury's estimations of α-monoglycerides or more likely of hydroxyl values were inexact, and that this error led to the correct assumption of random esterification The computation of di- and tri-glycerides from hydroxyl values is thus open to criticism whether the amount of β-monoglycerides is known or not A direct estimation of mono-, di- and tri-glycerides seems to be required

Another issue raised by Biswas and Ganguly is the esterification-rate of various fatty acids Their experiments show that fatty acids of medium molecular weight (such as lauric) and unsaturated acids (oleic, linoleic) react with glycerol faster than high molecular saturated acids (stearic) They attribute these differences to the higher solubility of glycerol in lauric and oleic acids than in stearic acid This opinion and similar views on the effects of the solubility of glycerol in fats[8] are based on a fallacy Admittedly, on the weight basis the solubility of glycerol in fats rich in stearic acid is lower by about one-tenth than in fats rich in lauric acid[9] On the basis of molar equivalents, however—and this is the basis of Biswas and Ganguly's own kinetic measurements—the solubility of glycerol in stearic acid is by one-tenth higher than in lauric and equal to that in oleic acid, which seems to dispose of Biswas and Ganguly's explanation According to earlier investigations[10,11], there is no appreciable difference between the reactivities of various fatty acids with methanol except those with less than four carbon atoms This has now been confirmed in this Laboratory in the case of glycerol by carrying out the esterification in high-boiling inert solvents The different rates of esterification of various fatty acids with glycerol in the absence of co-solvents appear thus to be due to factors other than the reactivity of fatty acids The investigation of these factors is in progress

BIOCHEMISTRY

Actinonin : an Antibiotic Substance produced by an Actinomycete

During a programme of screening of soil and other materials to select antibiotically active microorganisms, Drs R Green and R Bhagwan Singh, of the Institute for Medical Research, Kuala Lumpur, isolated a new species of an actinomycete, later classified under the serial number *Streptomyces* Cutter *C*/2 (N C I B 8845) It was active against a number of bacterial strains, including *Mycobacterium phlei* and *Staphylococcus aureus*

We have found that the organism grows well in deep culture at 30°–32° in a medium containing a source of nitrogen (for example, dried autolysed yeast) and a carbohydrate (for example, starch) in stirred, aerated flasks or fermentation vessels; such cultures show the same type of antibacterial activity as on plate culture, the activity being present practically exclusively in the medium

Isolation of the active substance (named 'actinonin') on a large scale (that is, from 300 l. of culture) proved to be a relatively straightforward matter. The material was completely transferable from the culture filtrate into *n*-butanol from which, after concentration, it was further purified by a series of partitions between aqueous solution and chloroform at different pH values, to give a final chloroform concentrate Solid actinonin was precipitated from this by addition of diethyl ether at 0° Treatment of the substance in hot ethanol solution with active carbon, followed by crystallization from ethanol-ether, gave fine white needles or colourless rods, m p 148°–149° (uncorr)

Actinonin is a faintly acid substance of molecular formula $C_{19}H_{35}O_5N_3$ It is stable in cold alkali, and not readily affected by cold dilute acid It is soluble in water, alcohols and pyridine, and is active in broth dilution against a number of Gram-positive and Gram-negative bacteria, including the following *St aureus* G, *Bacillus anthracis* 0/15, *Salmonella enteritidis*, *S typhosa*, *Streptococcus pyogenes* 0/8, *Klebsiella pneumoniae* 0/10, *M smegmatis*, *B C G*, *M phlei* 0/17 A F, *M phlei* 0/14 Minimum concentrations necessary to inhibit growth vary between 20 and 100 μg/ml It also inhibits the phages of a number of strains of *St aureus* at concentrations down to 0 25 μg/ml It has no apparent toxicity to mice in doses up to 400 mg/kg body-weight

Inorganic Phosphate and the Rate of Glycolysis in Insect Muscle

CHANGES in the level of inorganic phosphate are believed to be responsible for the Pasteur effect in various cells metabolizing glucose, for example, in yeast[1], ascites tumour cells[2], and bacteria[3] A similar mechanism is, however, difficult to accept for insect thoracic musculature where the anaerobic increase of glycogen breakdown was shown to occur without any simultaneous change in the level of inorganic phosphate[4] In experiments reported here, evidence was found that the level of inorganic phosphate is rate-limiting for the anaerobic glycolysis in this tissue

In preparations of the intact metathoracic musculature of the cockroach *Periplaneta americana*[4], changes in the acid-soluble phosphorus compounds were followed during anaerobiosis and in subsequent recovery in oxygen Phosphorus compounds were labelled by injecting the animals with phosphorus-32 a week prior to the experiment, after this period, the labelling of all soluble phosphorus compounds was practically uniform[5] The neutralized perchloric acid extract was subjected to paper ionophoresis and the radioactivity of the spots of various phosphorus compounds was taken to be proportional to their absolute amounts Determination of the absolute content of a single compound (colorimetric determination of inorganic phosphate with the butanol extraction method[4] or colorimetric determination of arginine phosphate[6]) allowed calculation of the absolute amounts of all other soluble phosphorus compounds

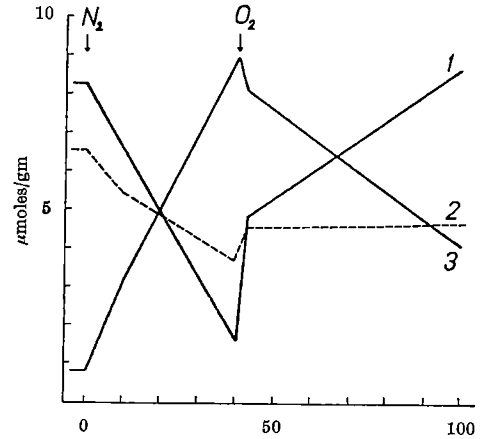

Fig 1 Changes in the level of arginine phosphate (1), adenosine triphosphate (2), and glycerophosphate (3), in metathoracic musculature of *Periplaneta* in anaerobiosis and after oxygen re-admission (marked by arrow)

It was confirmed that the total amount of soluble phosphorus remains unchanged during 40 min anaerobiosis and that the main change in these conditions is the breakdown of arginine phosphate and adenosine triphosphate and synthesis of glycerophosphate[7] (Fig 1) The amount of glycerophosphate synthesized is exactly equivalent to the amount of the energy-rich compounds broken down and the level of inorganic phosphate does not change significantly after transition into anaerobiosis (Fig 2)

After re-admission of oxygen, arginine phosphate is rapidly resynthetized, the resynthesis being complete after 1 hr The resynthesis of adenosine triphosphate is incomplete, evidently because only a small amount of adenosine diphosphate accumulates in the tissue during anaerobiosis most of it appears to be converted via adenosine monophosphate to inosine monophosphate and further dephosphorylated The re-oxidation of glycerophosphate in the tissue was found to be a rather slow process, thus little phosphate is liberated from it in the first

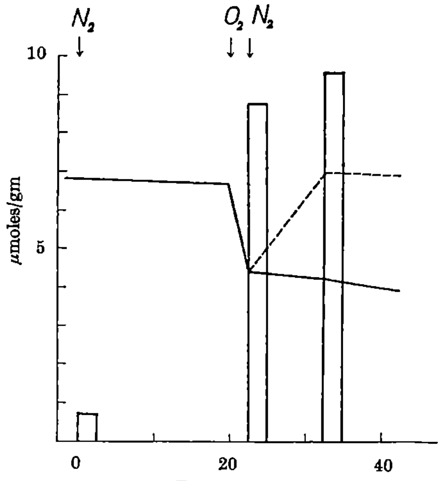

Fig 2 The level of inorganic phosphate in metathoracic musculature of *Periplaneta* in anaerobiosis and after re-admission of oxygen (full line) and in repeated anaerobiosis (broken line) Columns represent the respective levels of glycerophosphate in the experiment with repeated anaerobiosis

minutes after oxygen re-admission and the synthesis of arginine phosphate in this time occurs at the cost of inorganic phosphate, which sinks rapidly considerably below the original level (Fig 2) This shows that a considerable amount of it is available for metabolism, at least for oxidative phosphorylation

Further experiments were designed to show whether glycolysis in this tissue can proceed at this lowered level of inorganic phosphate After 20 min anaerobiosis (at this point the process of glycolysis is still approximately linear) the preparations were transferred for 2 5 min into oxygen and then into nitrogen again The level of inorganic phosphate returned rapidly to the original level, whereas in oxygen it remained lowered for at least 20 min , this shows that in the first 10 min of the second exposition to nitrogen the breakdown of the phosphorus compounds exceeded their synthesis, that is, that glycolysis was slowed In accordance with this, the rate of glycerophosphate accumulation decreased considerably in this period (Fig 2)

The rapid return of inorganic phosphate exactly to the original level favours the hypothesis that inorganic phosphate is the rate-limiting factor of anaerobic glycolysis in this tissue After transition into anaerobiosis the tissue cannot synthesize glycerophosphate at the expense of inorganic phosphate, and therefore the rate of glycolysis is limited by the rate of breakdown of the macroergic phosphorus compounds, the level of inorganic phosphate remains constant If anaerobiosis is introduced at the moment when the inorganic phosphate is lowered, glycolysis is slowed and the splitting of the macroergic phosphates exceeds glycerophosphate synthesis until the inorganic phosphate reaches its original level, in this moment, the steady state is again established and the level of inorganic phosphate then remains unchanged

The assumption that inorganic phosphate is the rate-limiting factor of anaerobic glycolysis in normal muscle is further supported by experiments with 2,4-dinitrophenol This substance is known to enhance the anaerobic glycogen breakdown in this tissue twice[8], this observation eliminates the possibility that in normal muscle some of the glycolytic enzymes are rate-limiting, since dinitrophenol is not known to interact with any of the glycolytic enzymes[9] The anaerobic increase of the glycolytic rate after application of dinitrophenol was found to be accompanied by an increase of the level of inorganic phosphate from 7 0 to 8 9 μmoles/gm as a result of accelerated dephosphorylation of macroergic phosphates, this is in agreement with the hypothesis suggested here

Liver Ribonuclease and Deoxyribonuclease Activity of Vitamin B_{12}-Deficient Chicks: Effects of Orotic Acid and Methionine

One of the most interesting aspects of the nutritional and metabolic relationship between vitamin B_{12}, orotic acid and methionine observed in chicks[1] concerns the participation of these factors in nucleotide metabolism In fact, at the level of this metabolism, both orotic acid and methionine have effects quite similar to those of vitamin B_{12} in chicks deficient of this vitamin increase of the liver RNA content and of the nucleotide content of the acid-soluble fraction[2], as well as increase in rate of turnover of these structures[3] These results induced us to consider nucleotide metabolism as a common field of action of these three substances and to try to explain the nutritional relationships observed between them

To get a better idea of the mechanisms through which vitamin B_{12}, orotic acid and methionine act on nucleotide metabolism, a series of investigations were undertaken on the effects which these three substances have on the enzymes, related to this metabolism

The present communication concerns the experiments on the effect of vitamin B_{12}, orotic acid and methionine on the liver ribo- and deoxyribo-nuclease activity in B_{12}-deficient chicks This work is of particular interest owing to the essential part that these enzymes play on the normal balance between synthesis and degradation of the polynucleotide structures

Our experiments were performed on the liver of New Hampshire × White Leghorn chicks

The animals were divided into 4 groups according to their body-weight One group was kept on the B_{12}-deficient diet[4] and the other three were fed the same diet supplemented, in the case of each group, with 10γ vitamin B_{12}, 10 mgm orotic acid, 150 mgm of DL-methionine per 100 gm respectively

At the end of the experiment (5 weeks), the animals were killed and their livers were homogenized at 0° C. in a glass Potter apparatus with 0 1 *M* sodium acetate buffer *p*H 5 Ribonuclease was assayed at 37° C , 1 ml of homogenate (5 per cent) and 2 mgm of purified RNA in a total volume of 2 ml were incubated The reaction was stopped after 30 min by adding 2 ml of ice-cold 10 per cent perchloric acid containing 0 25 per cent uranile acetate The mixture was centrifuged after 1 hr in the cold and the extinction of supernatant read at 260 mμ in a Beckman *DU* spectrophotometer

Deoxyribonuclease was measured in a similar way; 2 ml of ice-cold 10 per cent perchloric acid were used for stopping the reaction and the mixture was left for 10 min in the cold before centrifuging Appropriate blanks were determined in these assays and subtracted from the observed values[5]

Table 1 LIVER RIBONUCLEASE AND DEOXYRIBONUCLEASE ACTIVITY OF CHICKS

Group No	Supplement/ 100 gm diet	Ribonuclease activity*	Deoxyribonuclease activity*
1	—	4 66 ± 0 43†	1 62 ± 0 14
2	10γ vitamin B_{12}	5 08 ± 0 09	2 92 ± 0 29
		t = 1 06, P > 0 3	t = 13, P < 0 001
3	10 mgm orotic acid	5 13 ± 0 07	2 04 ± 0 10
		t = 1 07, P > 0 3	t = 2 4, P < 0 05
4	150 mgm DL-methionine	5 51 ± 0 42	2 03 ± 0 27
		t = 1 4, P < 0 2	t = 1 3, P > 0 2

* Ribonuclease and deoxyribonuclease activity is expressed as the increase in optical density at 260 mμ of the acid-soluble supernatant produced by 1 gm (wet weight) of tissue in 30 min under the condition of assay. The values are the mean of six animals

† *S E*

The results show that the vitamin B_{12}, the orotic acid and the methionine exert no effects on liver ribonuclease activity, in fact the values for the B_{12}-deficient animals do not show significant variation from those of treated animals On the contrary, vitamin B_{12}, orotic acid and methionine seem to exert a certain action on the activity of deoxyribonuclease In fact the values of this enzymatic activity in the livers of treated animals are significantly higher than those of deficient animals

On the basis of these results we believe that the observed increase of the liver RNA content of treated animals as compared with the deficient animals is due to the effect of vitamin B_{12}, orotic acid and methionine on the biosynthetic process rather than on those of degradation

With regard to DNA, since the content of these structures does not show any variation in the livers of deficient and treated animals, even if in the latter the deoxyribonuclease activity is higher, one is tempted to think that vitamin B_{12}, orotic acid and methionine enhance not only the catabolic processes but also the anabolic processes, so that the DNA content of the cells remains practically the same

Nucleic Acid Content of Inflammatory Cells

IT is generally known that, during the inflammatory process, morphologically different cell-types appear in a certain sequence in the exudate Recently, on the basis of autoradiographic experiments, Speirs *et al* [1] have reported that eosinophil polymorphonuclear cells were phagocytized by mononuclear cells and this phenomenon is probably responsible for the synthesis of antibodies in these cells

In our experiments sterile paraffin-oil was injected intraperitoneally into rabbits and the cells which appeared in the exudate were collected in various periods of inflammation The cells obtained on the first day were, morphologically, mainly polymorphonuclear leucocytes, on the third day a mixture of about equal numbers of polymorphonuclear and mononuclear cells, and ultimately on the fifth day a fairly pure mononuclear cell population was found

The cells were washed with saline at 4° C and their nucleic acids were isolated by the Schmidt–Tannhauser method, the ribonucleic acid phosphorus was determined by the orcinol reaction and the deoxyribonucleic acid phosphorus by the indole reaction In addition, the fractions of acid-soluble nucleotide, the lipid-phosphorus (using Griswold's method) and the protein (using Lowry's method) were determined

Some characteristic results are given in Table 1, which demonstrates that the deoxyribonucleic acid phosphorus content of the cells is essentially constant, but the ribonucleic acid phosphorus content varies in the different cell-series, that is, it increases three- to four-fold in mononuclear cells[2] On the basis of protein content a certain difference appears to exist between the mononuclear series In some series the increase in content of ribonucleic acid is not followed by the increase in content of protein, and in others the content of protein is also increased significantly

Acid-catalysed Reaction of Reduced Pyridine Nucleotides

IN a recent publication[1] it was demonstrated that the catalysed reaction of DPNH and TPNH in weakly acidic buffers follows first order kinetics, and that the rate of the TPNH reaction at constant acidic pH is considerably greater than that of DPNH Almost simultaneously. other authors published similar results[2] The results of a more detailed comparison of the rates for the reduced nucleotides are given in Fig 1 For TPNH the relationship is log K_1 = 3 71–0 46 pH, for DPNH it is log K_1 = 3 67–0 49 pH, where K_1 is the first-order constant (t = sec) The figure represents results from experiments using three different lots of enzymatically reduced nucleotides (TPNH, 96 5 per cent DPNH, 99 per cent, Sigma and Co) For a particular nucleotide no essential difference of rates was noted in the following buffers

Table 1

Day of collecting	No determined	DNA-P / cell pg	RNA-P / DNA-P	Acid-soluble ribose / DNA-P	Lipid-P / DNA-P	Protein / DNA-P

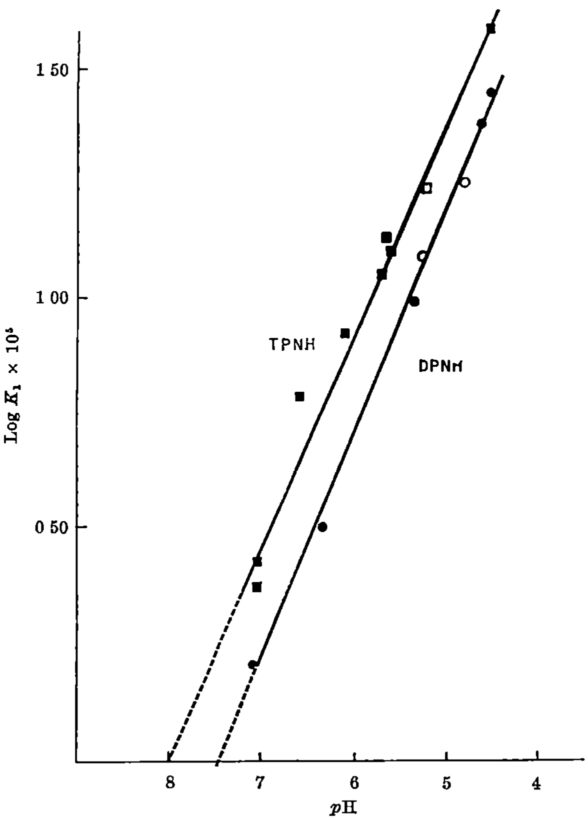

Fig. 1. Effect of pH upon the reaction-rate for TPNH and DPNH. 1 ml. of reduced nucleotide in distilled water at pH 8.0 was added to a 1-cm. silica cuvette, followed by 2 ml. of buffer of designated pH. The solutions were mixed by inversion and readings taken immediately at 340 mμ against a buffer blank. Equimolar concentrations were based on a molar extinction coefficient of 6.22 × 10³ (ref. 8). The pH measurements are final readings. Black squares and circles, phosphate buffer; white squares and circles, citrate buffer.

at equal concentration and pH: phosphate, citrate, *tris*-hydrochloride, and ethylenediamine tetraacetic acid. It is significant to observe that the two lines converge and, by extension, the rate of the reaction of the two nucleotides in 0.1 *N* hydrochloric acid theoretically would be indistinguishable experimentally. It is perhaps this which may account for the fact that the difference between the nucleotides has not been observed previously. By extrapolation, the theoretical pH, where the rate becomes zero for both nucleotides, may be obtained. Actually the rate never becomes zero, but the extrapolation may be useful in determining the constants in the overall rate equation. First-order kinetics were obeyed only at low pH where (H+) is not rate determining, and for small changes in nucleotide concentration.

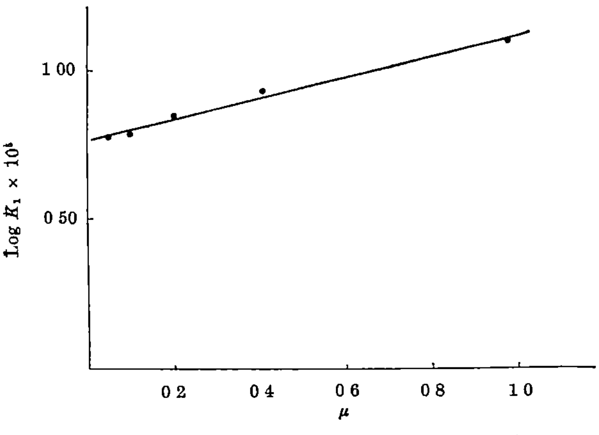

Fig. 2. Effect of ionic strength (μ) on the reaction-rate for DPNH. Citrate buffers of varying concentration prepared with the final pH adjusted to 5.36. Complete ionization for citrate is assumed.

The reaction-rate is influenced by the ionic strength of the medium in the same manner as has been reported for model analogues[3,4] (Fig. 2). It is conceivable that this effect of charge density may have some bearing in explaining the accelerated TPNH reaction-rate as compared with DPNH.

The reaction products of the reaction are at present unknown, although there is evidence that the reaction is sequential[5]. The reaction with a model analogue, 1-benzyl-3 acetyl-1,4-dihydropyridine[4], resulted in the addition of water across the double bond, placing a hydroxyl at position 6. This was believed to be followed by an acid-catalysed ring opening at position 6 forming the tautomeric amino aldehyde.

This sequence of reactions is in harmony with the present kinetic data, if one assumes that the acid-catalysed ring opening is rate limiting, for it could explain why log K_1 is proportional to $\sqrt{\mathrm{H}+}$ instead of (H+) through the formation of the weakly dissociating substituted amine salt. In addition, it explains the reported rise in pH accompanying the reaction[6]. On the other hand, Segal and Stein[7], using 1-benzyl-1-4 dihydronicotinamide as a model analogue, obtained a hydroxyl derivative in the 5 position which rules out the possibility of the tautomeric amine aldehyde and ring opening. It would thus appear that the ring substituents markedly affect the course of the reaction, and extrapolation of results from model analogues to the reduced nucleotides should be done with great caution.

One-Dimensional Starch-Gel Electrophoresis of Bovine Skim-Milk

Aschaffenburg and Drewry[1] found by paper electrophoresis that the milk of individual cows may contain either β-lactoglobulin *A* or *B* singly or a mixture of the two proteins. These authors presented evidence that the production of the β-lactoglobulins is controlled by two allelic autosomal genes[2].

By the technique of starch-gel electrophoresis of whole skim-milk, a distinct separation of the whey proteins can be obtained without any preliminary treatment of the skim-milk. Skim-milk samples from individual cows have been submitted to starch-gel electrophoresis for 5 hr. at 12 V./cm length of the gel, using the boric acid buffer of Smithies[3]. The

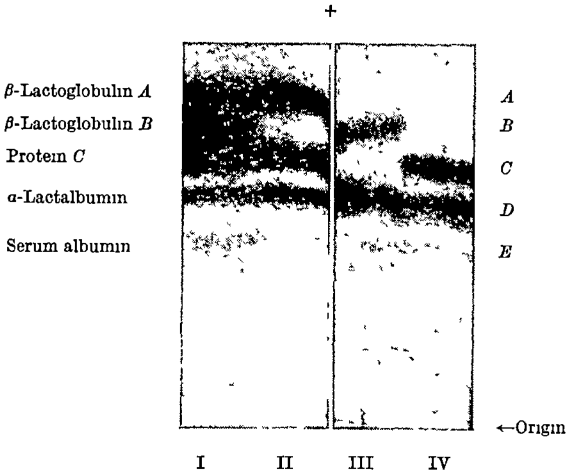

Fig 1 Starch-gel electrophoretic patterns of four skim-milks from individual cows Left to right I, A B C, II, A C, III, B, IV, C protein patterns

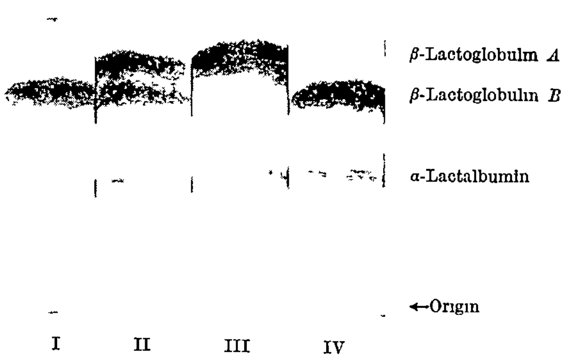

Fig 2 Paper electrophoretic patterns at pH 8 6 of the concentrated 'lactalbumin' solutions of skim-milk samples containing, left to right I, B, II, A C III, A, IV, C proteins on starch-gel electrophoresis

samples were applied on Whatman E 17 filter paper inserts which were removed from the gel 1 hr after the start of the electrophoresis

A comparison of the skim-milk and acid whey starch-gel electrophoretic patterns indicates that all, or at least the major, protein zones in the skim-milk pattern represent whey proteins The colloidal casein of milk does not enter the gel within the time the inserts remain in the gel The major protein zones in the starch-gel pattern of skim-milk are designated by the letters *A*, *B*, *C*, *D*, and *E* (Fig 1) and have been identified by a combination of the starch-gel electrophoresis of skim-milk and paper electrophoresis at pH 8 6 of the concentrated 'lactalbumin' solution Zone *A* is identical with β-lactoglobulin A, whereas zones *B* and *C* migrate at the same rate and in the position of β-lactoglobulin *B* (Fig 2) It can be shown that zones *D* and *E* represent α-lactalbumin and serum albumin respectively

Paper electrophoresis of the concentrated 'lactalbumin' solutions of milks containing *A*, *AB*, *AC*, *B*, *BC*, *C*, and *ABC* proteins on starch-gel electrophoresis was carried out to determine the corresponding β-lactoglobulin types (Table 1) Aschaffenburg and Drewry[4] have demonstrated by paper electrophoresis that all the proteins with the exception of the β-lactoglobulins are precipitated from the 'lactalbumin' filtrate when the pH is reduced to approximately 2 However, protein *C* as well as *A* and *B* is resistant to this low pH, further indicating the similarity of proteins *A*, *B*, and *C* Any of the proteins *A*, *B*, or *C* may be either present or absent in the milk of individual cows, suggesting that they are genetically determined From the genetical point of view, it is of interest that all three proteins have been found to occur together in one milk Two Jersey cows in different herds have been found which lack both *A* and *B* proteins in the milk, but protein *C* was present in each case (Fig 1)

Table 1

Starch gel electrophoretic pattern	β-Lactoglobulin type (ref 2)
A	*A*
A B	*A B*
A C	*A B*
B	*B*
B C	*B*
C	*B*
A B C	*A B*

Some of the milks containing protein *C* have been sampled at monthly intervals throughout the lactation period and the *A B C* patterns remain constant It would appear that protein *B* represents β-lactoglobulin *B*, as it occurs with greater frequency than protein *C* in the herds studied This new protein, *C*, was found in 24 out of 135 Jersey cows, but it was only detected in one of 85 Australian Illawarra Shorthorns From Table 1, it is obvious that the existence of protein *C* in the population may lead to an excess of β-lactoglobulin *B* if determined only by the paper electrophoretic method[2] The mode of inheritance of these proteins is being determined and will be presented later

This work was carried out during the tenure of a United Graziers' Association fellowship and supported by a grant from the Rural Credits Development Fund of the Commonwealth Bank of Australia

Liver Enzymes in Biliary Retention

The toxicity of bilirubin has been demonstrated in animals It is known to inhibit brain respiration *in vitro*[1], and to uncouple oxidative phosphorylation in isolated mitochondrias[2] Its cytotoxic action on almost every cell in the animal has been recently emphasized by Rozdilsky[3]

In man, damage, resulting from biliary retention, on the liver, has been established for a long time and is known to end in biliary cirrhosis, bile appearing thus as a potent hepatotoxine[4]

The actual toxicity of bile for the liver cell in the early stage of biliary retention has been tested by estimation of several liver enzymes in cases of biliary obstruction in man

Liver biopsies were taken from patients undergoing various surgical treatments for calculus of the choledocus or malignant disease of the pancreas or the bile ducts Biopsies were taken at the onset of operation and immediately prepared for enzymes assays Thorough pathological examination was carried out on the same piece of liver which was used for enzymatic investigations Whenever cirrhosis or any specific lesion was present, with the exception of biliary retention itself, the case was discarded and considered inadequate for enzymology Obviously enough, sclerosis, steatosis, malignant or inflammatory infiltration as well as any condition which disturbs liver structure is to be expected to modify the ratio of hepatocytes to other cells and therefore makes the estimation of enzymes meaningless The following enzymes were estimated alcohol dehydrogenase (ADH), glutamic dehydrogenase (GDH), lactic dehydrogenase (LDH), isocitric dehydrogenase (IDH), glutamic pyruvic transaminase (GPT) and glutamic-oxalacetic transaminase (GOT), glutaminase I (phosphate activated), and ornithine-carbamyl-transferase (OCT) Activities are referred to 1 gm fresh liver

Table 1

Enzymes	Normal subjects No of cases, 15		Biliary retention No of cases, 10
ADH	Range, 262 9–350 3 Mean value (m v), 306 6 ± 43 7	*P* 0 01	Range, 54 1–92 1 m v , 73 1 ± 19
GDH	280–377 5 m v , 329 1 ± 48 4	*P* 0 01	163–218 m v , 190 6 ± 27 4
LDH	3,065–4,805 6 m v., 3,935 4 ± 48 4	*P* 0 01	1,295–2,129 m v , 1,712 ± 417
IDH	728 8–901 2 m v , 815 ± 86 2	*P* 0 01	425 2–599 6 m v , 512 4 ± 87 2
GOT	154 682–190 746 m v , 172 714 ± 18 032		133 931–267 211 m v , 200 571 ± 66 640
GPT	57 804–83 910 m v., 70 857 ± 13 053		59 985–96 871 m v , 78 428 ± 18 443
Glutaminase	11 2–15 6 m v , 13 4 ± 2 2		9 5–21 9 m v , 15 7 ± 6 2
OCT	22 7–25 1 m v , 23 9 ± 1 2		21 6–24 m v , 22 8 ± 1 2

Results are expressed for the dehydrogenases in μmoles of substrate hydrolysed/hr /gm fresh liver, for the transaminases in Wroblewski spectrophotometric units, for glutaminase and ornithine-carbamyl-transferase in terms of μmoles of N-NH_3 evolved/hr at 37°/gm fresh liver

As shown in Table 1, ADH is reduced in all cases of biliary retention to a quarter of its normal value The latter was calculated on the basis of fifteen estimations made in patients free of biliary retention and operated on for various diseases in which liver was not involved GDH is reduced to almost half its normal value as is also IDH, while LDH activity has to be divided by a factor of 2 5

In contrast with the dehydrogenases, both transaminases show no significant change and GOT is, if anything, increased Glutaminase and OCT are very close to normal and do not appear to be modified by biliary retention

These results suggest that bile *per se*, whatever the cause of the retention, suffices to produce striking enzymatic changes in the liver cell, possibly by altering respiration or permeability to substrates or co-factors

It is noteworthy that toxicity of bile for enzymes is selective transaminases, glutaminase and OCT are not affected while the dehydrogenases are

Whether enzyme inactivation is due to temporary inhibition by bile or to the actual destruction of the enzyme cannot be asserted from our work This point is being further investigated by comparing activities in the course of jaundice and after treatment Yet it is clear that prolonged biliary retention will result in aggravation of the enzymatic lesion and of the cell thereafter

In most cases the severity of damage caused to the enzymes was found to be proportionate to the degree of biliary retention as assessed by the levels of bilirubin in blood, and independent of the cause of the retention, whether malignant or not

The nature of the bile component or components involved has not been revealed by our experiments

We have tested the action of pure bile on all enzymatic reactions reported herein Bile was obtained, aseptically, by puncture of the gall bladder, and diluted 50 times before it was added to the reaction It showed no inhibition whatsoever in the normal, nor in patients with biliary retention

It is concluded that toxicity of bile on enzymes is mediated through the intact liver cell and has no effect on homogenates at the concentrations used

Serotonin Degradation by Homogenates of Tissues from *Heloderma horridum*, the Mexican Beaded Lizard

IN a previous report[1], the finding of serotonin and of amine oxidase activity in the venom of *Heloderma horridum* was recorded The purpose of this communication is to present results of studies which demonstrate that tissue homogenates of selected organs from two animals of this species degrade serotonin readily in an *in vitro* test system In addition, the findings with respect to efforts to inhibit this activity with various compounds will be noted

The beaded lizards were sexually mature females that had been in captivity for more than a year They were killed by bleeding, and various biochemical and hæmatological values of their blood were determined[2] Immediately after bleeding, the respective organs were removed and rinsed with physiological saline solution The organs were then individually homogenized in a Waring blender in 2 vol of physiological saline solution and frozen at − 20° C This material was thawed at the time of testing, and serial 2-fold dilutions of the homogenates were made in physiological saline solution Evidence for serotonin degradation was sought by employing 300 μgm serotonin creatinine-sulphate as substrate for the respective homogenate dilutions and analysing for residual serotonin by the method of Udenfriend *et al* [3] The determinations were made at *p*H 7 4 Homogenates of striated muscle, liver, œsophagus, stomach, intestine and pancreas were tested Marked serotonin degradation occurred with homogenates of each of these tissues This finding was not unexpected in view of the widespread distribution of monoamine oxidase activity in other animal tissues[4] However, it should be noted that striated muscle from *H horridum* was active in this regard in contrast to human striated muscle, which does not exhibit this capability in the same test system[5]

In an effort to characterize further the pathways by which these homogenates metabolize serotonin, a series of tests with various enzyme inhibitors was performed The test procedure was as follows homogenate dilutions which had been found on prior titration to metabolize between 65 and 80 per cent of the substrate were used in the test system One ml of the homogenate dilution was added to a 20-ml beaker with 1 0 ml of 0 5 *M* phosphate buffer (*p*H 7 4) and 0 5 ml of the solution containing the substance to be tested for inhibition of the reaction The beakers were pre-incubated for 15 min on a Dubnoff metabolic shaker Solutions of serotonin creatinine sulphate and the other test substances were freshly prepared and placed in the test system within 10 min of preparation Final concentration in the incubation mixture was 4 9 × 10^{-4} *M* for serotonin Incubation was continued for 1 hr and determination of residual serotonin was made as already described Controls included tests with boiled tissue homogenates, and, for colour interference, recovery of serotonin after incubation with the respective test substance in the absence of tissue homogenate The following substances were tested for reaction inhibition at a final concentration of 1 × 10^{-3} *M* iproniazid (IPZ), isoniazid (INH), hydralazine, procaine amide, mercuhydrin, and D,L-penicillamine Results are given in Table 1

Table 1 EFFECT OF CERTAIN ENZYME INHIBITORS ON SEROTONIN DEGRADATION BY INDICATED HELODERM TISSUE HOMOGENATES

Tissue Homogenate	Inhibition (per cent)					
	IPZ	INH	Hydralazine	Procaine amide	Mercuhydrin	Penicillamine
Striated muscle	35	14	0	8	3	35
Liver	30	15	0	0	67	22
Œsophagus	33	36	0	50	30	32
Stomach	49	16	46	55	48	34
Intestine	28	11	0	24	78	34
Pancreas	73	0	—	0	0	87

Iproniazid, procaine amide, and hydralazine are known monoamine oxidase inhibitors Isoniazid is not an inhibitor of monoamine oxidase activity, but it does impede the ceruloplasmin pathway of serotonin metabolism, as do the foregoing compounds[5] Mercuhydrin is believed to effect enzymatic activity through its metal moiety, while D,L-penicillamine is a chelating agent It is of interest that none of the compounds employed was found to inhibit completely the degradation of serotonin by any of the tissues tested It can be seen that marked inhibition of the enzymatic processes involved in the metabolism of serotonin by pancreatic homogenates was achieved with iproniazid and D,L-penicillamine, and by mercuhydrin in tests with hepatic and intestinal homogenates Lesser inhibition or no effect was detected in the remaining tests These findings suggest that channels of serotonin degradation other than monoamine oxidase are active in several organs of *H horridum*

Urea Synthesis in Rats treated with α-D,L-Methylaspartic Acid

α-D,L-Methylaspartic acid (MA) is a strong inhibitor of hepatic argininosuccinate synthetase, inhibition of this enzyme was first described by Braunstein *et al* [1], on the basis of *in vitro* experiments, in which 200 μmoles of MA were added to samples containing L-citrulline, L-aspartate, adenosine triphosphate (ATP) and a respiratory substrate, in presence of rat liver slices and homogenate

In this communication we report some results on the effect of *in vivo* administration of MA to rats of hepatic argininosuccinate synthetase, and urinary excretion of urea and ammonia Some of these results were objects of short communications at "VI^es^ Journées Biochimiques Latines" (Geneva, May 25–28, 1961)[2], and to the Fifth International Congress of Biochemistry (Moscow, August 10–16, 1961)[3]

MA (500 mg/kg of body-weight), in buffered solution at *p*H 7 4, was injected endoperitoneally into male albino rats, average weight 250 g, the animals were killed at various times after injection, the liver was quickly removed and cooled, and it was homogenized with M/15 phosphate buffer, *p*H = 7 4 (1 g tissue + 2 ml phosphate buffer) Samples were prepared in Warburg vessels, according to the following method enzymatic source, 0 5 ml of the homogenate (= 166 mg fresh weight tissue), $MgSO_4 7H_2O$, 10 μmoles, ATP, 5 μmoles, fumarate, 20 μmoles, L-citrulline, 20 μmoles, L-aspartate, 20 μmoles Final volume 3 ml, *p*H = 7 4 Samples were also prepared in which citrulline or aspartate were omitted A mixture of oxygen (95 per cent) and carbon dioxide (5 per cent) was then allowed to pass through the samples, and incubation was carried out at 37° C for 1 h Reaction was stopped by placing the vessels in iced water, and urea was determined on aliquots of the mixture, according to Krebs and Henseleit[4] At the same time, samples were prepared containing as enzymatic source the homogenate obtained by liver of control rats, which had been injected with an equal volume of phosphate buffer (*p*H = 7 4) in place of MA The results, reported in Table 1, show that endoperitoneal introduction of MA is capable of causing 100 per cent blockage of urea synthesis by citrulline and aspartate Inhibition is maintained totally until about the eighth hour after injection One deduces from the results reported, therefore, that to achieve total and permanent inhibition of hepatic argininosuccinate synthetase, injections must be repeated at intervals of 8 h The enzyme in question would thus be inhibited for a long time, and it would be possible to study the effects of inhibition on urea synthesis *in vivo*

Table 1 INHIBITION OF UREA SYNTHESIS BY CITRULLINE AND ASPARTIC ACID IN HOMOGENATES OF LIVER OF RATS TREATED WITH MA

H after injection	μmoles extra-formed urea in incubation mixture		Inhibition (per cent)
	Control rats	Rats treated with MA	
2	9 1	0	100
3	6 8	0	100
4	10 0	0	100
6	9 6	0	100
8	10 2	0	100
12	7 4	3 5	52

Male albino rats were kept in special metabolism cages, and uniformly fed, water was allowed *ad libitum*, the urine was collected daily, and urinary ammonia was determined according to Seligson and Hirahara[5], Kitamura and Iuchi's method[6] was used to estimate the urinary urea After some days, the rats which were excreting fairly constant quantities of urea and ammonia were isolated, and treated with MA (500 mg/kg body-weight, one injection every 8 h) The urine was collected 24 h after the first injection, and urea and ammonia were determined as before Table 2 shows the results of these experiments It appears that total quantities of urea and ammonia excreted in the urine by rats treated with MA do not differ significantly from the correspondent values in control rats (the same rats before treatment) It should be emphasized that in the livers of the treated animals argininosuccinate synthetase is blocked completely throughout the treatment (Table 1) Then, if the reaction between citrulline and aspartic acid were fundamental to the process of urea biosynthesis, that is, if it were necessarily involved in the path which leads from protein nitrogen to urea nitrogen, a stoppage, or at least a reduction, in urea formation would be expected when this reaction is blocked. Our results establish that this is not the case

Table 2 EXCRETION OF UREA AND AMMONIA IN RATS BEFORE AND AFTER TREATMENT WITH MA

mg urea per kg and per day		mg NH_3 per kg and per day	
Before treatment	After treatment	Before treatment	After treatment
1,119 ± 31	1,125	18 0 ± 0 5	17 9

In addition, preliminary results of Cedrangolo and co-workers[7], show that treatment with MA (500 mg/kg body-weight) is able to inhibit urea synthesis in liver also by carbamylphosphate (CP), ornithine and aspartate These results, if considered in the light of those exposed in this paper, throw doubt also on the role of CP as the donor of the first nitrogen atom of urea

Our experimental data results are in contradistinction to all the assumptions concerning the mechanism of urea synthesis held as valid up to now, and there is need for a comprehensive theoretical interpretation in the light of the problem of terminal nitrogen metabolism in mammals

Aspartic Transcarbamylase from Lettuce Seedlings : Case of End-Product Inhibition

ASPARTIC transcarbamylase (ATC-ase) an enzyme which catalyses the carbamylation of aspartic acid by carbamylphosphate (CAP) to yield carbamylaspartic acid (CA) is known in micro-organisms and animals[1] Its presence in higher plants has been mentioned[1] but, so far, has not been investigated to any extent

Lettuce seedlings, var Grand Rapids, were grown for 3–5 days in darkness at 26° C The enzyme was extracted by homogenizing the entire seedlings in a mortar and pestle or with an 'Omnimixer' using a buffer-sucrose solution The homogenate was transferred through gauze and centrifuged at 300*g* to remove the cell debris

precipitate	+ asp	43	1	
100,000*g* super-	− asp	85		
natant	+ asp	125	40	0 53

1 gm of 5-day-old seedlings was homogenized in 10 ml phosphate buffer (0 1 *M*, *p*H 7 0) sucrose 0 4 *M*, transferred through gauze and centrifuged at 300*g* for 8 min. The supernatant was made up to 20 0 ml and 15 0 ml were centrifuged at 20,000*g* for 30 min The precipitate was dispersed in 5 0 ml of the same buffer The 20,000*g* supernatant was centrifuged at 100,000*g* for 45 min. and the precipitate dispersed in 2 0 ml buffer

The reaction mixture contained 80 µmoles potassium pyrophosphate buffer at *p*H 9 0, 5 µmoles of aspartic acid where indicated, 5 µmoles of CAP (specific activity 76,000 c p m /µmole), and 0 5 ml of enzyme in a total volume of 0 75 ml The reaction mixture was incubated for 10 min at 37° C when 0 5 ml of 20 per cent TCA was added to stop the reaction The tubes were then heated for 6 min at 80°–90°, and centrifuged in the cold Of the decanted supernatant, 0 05 ml was plated on glass planchets, dried and counted in a thin end window Geiger–Muller tube

* Corrected for counts present in the absence of aspartic acid, and those due to the non-enzymatic reaction

ATC-ase activity was measured by following the increase in acid-stable radioactivity (CA) according to the method of Lowenstein and Cohen[2], where CAP labelled with carbon-14 and unlabelled aspartic acid are substrates Radioactive CAP was synthesized from ^{14}C-urea[3,4] and, except for the use of trichloroacetic acid (TCA) as deproteinizing agent rather than hydrochloric acid, the assay method was not changed By electrophoresis of the deproteinized reaction mixture on paper and autoradiography of the paper, it was found that the radioactive product is indeed CA Controls without aspartic acid as well as controls without enzyme (for following the chemical non-enzymatic reaction) were routinely performed

It was found that about 25–30 per cent of the activity of ATC-ase is located in the 300–20,000*g* particulate fraction and the rest in the 100,000*g* supernatant (Table 1) This partition of activity remained the same when different media were used during homogenation: tris buffer 0 1 *M*, *p*H 8 0–sucrose 0 25 *M*, or phosphate buffer 0 1 *M*, *p*H 7 0–sucrose 0 4 *M* with or without versene 0 01 *M* This particulate fraction activity remained practically constant on washing and reprecipitation Osmotic shock, treatment with digitonin, and freezing and thawing did not change the activity When the 300–20,000*g* particulate fraction was refractionated

Table 2 END-PRODUCT INHIBITION OF ATC-ASE

Compound	Final concentration (*M*)	Percentage of inhibition
Cytidine-5′-phosphate	0 02	30
Cytidine-5′-phosphate	0 04	62
Uridine-5′-phosphate	0 0025	76
Uridine-5′-phosphate	0 005	90
Uridine-5′-diphosphate	0 015	56
Uridine-5′-triphosphate	0 01	8
Uridine	0 04	none
Cytidine	0 04	none
Guanine-5′-phosphate	0 04	none
Adenine-5′-phosphate	0 04	none
Phosphate	0 04	none

The enzyme used was an ammonium sulphate fraction of the 20,000*g* supernatant isolated between 25–60 per cent saturation and dissolved in a volume equal to half the volume fractionated Otherwise the experimental conditions as in Table 1.

by centrifugation, 70 per cent of the activity was found in the 2,000–20,000g precipitate suggesting that the particulate enzyme may be located in the mitochondria[5] About 90 per cent of the mitochondrial enzyme can be rendered soluble by freezing and thawing It will be of interest to see if the mitochondrial and cytoplasmic enzymes have separate physiological roles

Some of the characteristics of the enzyme of the cytoplasmic fraction were studied next Its pH optimum is between 9 and 10, the K_m for aspartic acid was found to be 6×10^{-4} M and for CAP 2×10^{-3} M. The enzyme is markedly inactivated by dialysis (up to 80 per cent) This is probably not due to losing a co-factor because passage of the enzyme over a 'Sephadex G-25' column produces only a small loss of activity (about 15 per cent) Heating the enzyme for 5 min at 80° C causes an inactivation of 90 per cent The enzyme is inhibited by iodoacetic acid and also by maleic and succinic acids resembling the ATC-ase from *Streptococcus faecalis*[6]

ATC-ase is the first enzyme in the biosynthesis of pyrimidines in bacteria and mammals[1] Yates and Pardee[7] first observed, using a crude extract, that *E coli* ATC-ase is inhibited by cytidine-5′-phosphate This inhibition is thought to be a physiologically significant regulator of pyrimidine biosynthesis in bacteria well known as feedback or end-product inhibition[8]

End-product inhibition has not been observed previously in higher plant enzymes[9], but, on the basis of the data presented here, it seems reasonable to suggest that this regulatory mechanism exists here also As can be seen in Table 2, ATC-ase from lettuce seedlings is inhibited strongly by various pyrimidine nucleotides The inhibition appears to be specific for pyrimidine nucleotides since the respective nucleosides and two purine nucleotides as well as orthophosphate do not inhibit Uridylic acid is at least ten times as potent an inhibitor as cytidylic acid, and the inhibitory activity among the uridine compounds decreases with increasing phosphorylation These last two features of the ATC-ase from lettuce seedlings differ markedly from the ATC-ase from *E coli*[7,10], which is sensitive to cytidine rather than uridine nucleotides and where the inhibition increases with increasing phosphorylation Whether the inhibition specificity for different end-products reflects a variance in the amount of free nucleotides present in the cell sap of *E coli* and lettuce seedlings remains to be ascertained

PHYSIOLOGY

Endocrine Control of the Plasma Albumin/Globulin Ratio

REVERSAL of the albumin/globulin ratio is commonly encountered in Africans in different parts of the continent of Africa This reversal is ascribed in large measure to malnutrition and/or infection Whatever the cause, the mechanism for this reversal still remains obscure

Since we had indicated previously that the fatty liver of kwashiorkor is more than likely dependent on a particular endocrine configuration, induced by whatever is responsible for the acute episode of kwashiorkor[1], the possibility was entertained that the reversed albumin/globulin ratio might also be linked in some way to a particular endocrine physiology Accordingly, this possibility was investigated in baboons

Ten normal and three totally hypophysectomized baboons were used in this work The normal animals were housed under standard conditions in the colony The operated animals remained in a constant-temperature room overnight

A transpalatine approach was used to expose the hypophysis and the gland was removed under direct vision Five and a half months after hypophysectomy, B413 received 20 mgm hydrocortisone daily for seven weeks

Oxalated blood samples for electrophoresis and for estimation of total serum protein, albumin and globulin were always collected at 9 o'clock each morning, 16 hr after the last meal

Paper electrophoresis was carried out on hanging strips of Whatman filter paper No 1 in veronal buffer (0 05 M pH 8·6) for 16 hr The paper strips were stained with bromophenol blue A Zeiss densitometer was used for the photometry of stained strips Total serum protein and albumin concentrations were estimated by the biuret method and the globulin level was obtained by difference

Serum protein analyses were performed on ten normal baboons The mean total protein (6 94 ± 0 47 gm per cent), albumin (3·74 ± 0 31 gm per cent) and globulin (2 71 ± 0 32 gm per cent) concentrations and the albumin/globulin ratio (A/G ratio) were determined together with their standard deviations (Table 1) Similar estimations were performed on three hypophysectomized baboons, from seven to twenty-six weeks after the operation The total serum protein concentrations of B413, B450 and B390 were significantly lower than those prior to hypophysectomy, being 5 28, 6 14 and 5 98 gm per cent respectively The albumin concentrations of all three hypophysectomized animals (1 30–2 04 gm.

Table 1 SERUM PROTEIN CONCENTRATIONS IN NORMAL AND HYPOPHYSECTOMIZED BABOONS

† Electrophoresis

per cent) were significantly lower and the globulin levels (3 36–4 68 gm per cent) higher than normal The A/G ratio (1 378 in normal baboons) was markedly depressed to values between 0 278 and 0 571 (Table 1) Furthermore, γ-globulin concentrations in the operated animals, seven or more weeks after hypophysectomy, were significantly elevated above the normal level of 18 3 per cent of total protein[2] γ-Globulin concentration in *B*413 had risen to 26 8 per cent of the total protein, to 33 10 per cent in *B*450 and to 50 3 per cent in *B*390 (Table 2)

*B*413 received 20 mgm hydrocortisone daily for seven weeks Both the total protein and albumin concentrations rose to levels well within the normal range (6 50 and 3 40 gm per cent respectively) Weekly estimations of serum proteins, furthermore, showed the globulin concentration to have decreased by 0 48 gm per cent to a level of 3 10 gm per cent, which may be considered normal The increasing albumin and decreasing globulin concentrations during the period of hormone treatment are thus reflected in the changing A/G ratio, which rose from 0 622 to 1 098 (Table 3)

Table 3 EFFECT OF HYDROCORTISONE THERAPY ON HYPOPHYSECTOMIZED BABOON, *B* 413

Treatment	Total protein (gm %)	Albumin (gm %)	Globulin (gm %)	Albumin / Globulin
Nil	5 80	2 22	3 58	0 622
Hydrocortisone 20 mgm /day				
After 2 weeks	6 04	2 64	3 40	0 741
After 4 weeks	6 26	2 84	3 42	0 829
After 5 weeks and 2 days	6 38	3 28	3 10	1 058
After 6 weeks and 2 days	6 42	3 44	2 98	1 149
After 7 weeks and 2 days	6 50	3 40	3 10	1 098

Long-standing hypophysectomy in three baboons caused a reversal of the albumin/globulin ratio This change is reflected both by a decrease of the serum albumin and an increase of the serum globulin concentration, which in large measure is a reflexion of an increase in γ-globulin, while the total serum protein-level was slightly depressed

Levin and Leathem[3] concluded from their work on both adrenalectomized and hypophysectomized rats that alterations in the serum protein pattern following hypophysectomy could be attributed to an adrenal as well as a thyroid effect They suggested that in the rat the serum albumin-level is maintained under adrenocortical influence while the serum globulin-level is associated with activity of the thyroid gland Following hypophysectomy a change in both fractions occurs because of the decrease of both adrenocortical and thyroid activity

Hartman *et al* [4] demonstrated a drop in serum albumin and a rise in serum globulin following adrenalectomy in rats In one of our hypophysectomized baboons, the elevated serum globulin was reduced to within the normal range after treatment with hydrocortisone Indeed, the albumin concentration was more markedly affected than the globulin by hydrocortisone therapy. Albumin concentration rose by nearly 1 2 gm per 100 ml serum but the globulin-level was decreased by 480 mgm per 100 ml serum.

In view of the observations in baboons cited here, the reversed albumin/globulin ratio in kwashiorkor, like the fatty liver, is most probably dependent on a particular endocrine physiology which emerges in malnutrition and in kwashiorkor

β-Hydroxybutyrate and Sodium Citrate as Stimuli of the *in vitro* Secretion of Insulin

BRACHMACHARI *et al* [1,2] have shown that certain metabolites like β-hydroxybutyrate, citrate, isocitrate and succinate, when injected into the animal (rabbit), produce hypoglycæmia, and this is interpreted as being due to a stimulus of the secretion of insulin β-Hydroxybutyrate and citrate, according to the aforementioned experiments, seem to act, directly or indirectly, by different mechanisms, in view of the fact that the effect obtained is considerably more with citrate than with β-hydroxybutyrate and because this metabolite seems to increase first the content of active insulin/gm of pancreas

As we have shown that pancreas slices when incubated *in vitro* respond to certain stimuli (with insulin secretion) we thought it would be interesting to find out if β-hydroxybutyrate and citrate, when added to the buffer surrounding pancreas slices, produce an increase in secretion of insulin

Table 1 INSULIN EFFECT OF THE INCUBATION BUFFER PLUS β-HYDROXYBUTYRATE OR SODIUM CITRATE SURROUNDING PANCREAS SLICES (No of experiments in parentheses)

Metabolites	Glucose uptake (mean)		
β-Hydroxybutyrate $4 \times 10^{-4} M$ (30)	0 470	± 0 017	$P > 0 05$
Control	0 436		
Sodium citrate $1 \times 10^{-3} M$ (20)	0 574	± 0 029	$P < 0 01$
Control	0 388		
Sodium citrate $7 \times 10^{-5} M$ (30)	0 331	± 0 013	$P = 0 01$
Control	0 281		

The technique already described[3] was adopted, using concentrations of citrate of 1×10^{-3} and $7 \times 10^{-5} M$ and $4 \times 10^{-4} M$ of β-hydroxybutyrate As can be seen in Table 1, the citrate causes secretion of insulin, but not β-hydroxybutyrate, at the given dosage This fact suggests to us that if both metabolites cause secretion of insulin in the animal, it does so by different mechanisms Possibly by an indirect way in the case of the β-hydroxybutyrate and by a direct mechanism in the case of the citrate It could be by synthesis of adenosine triphosphate

Correlation of the Effects of Insulin and of Muscular Contraction *in vitro* on Uptake of Glucose by the Frog

Heimreich and Cori[1] and later R-Candela[2] among others have shown that the specificity to sensitive sugars is similar both with insulin and muscular contraction On the other hand, the great resistance of toads to insulin injections is known from the work of Rapela *et al* [3]. We have confirmed this finding in frogs injected with up to 40 U /100 gm without showing any signs of hypoglycæmia

These results inspired us to examine the possible correlation of the effects of insulin *in vitro* and of muscular contraction *in vitro* on uptake of glucose by the frog recti abdominis muscle

Frogs (*Rana esculenta* L) weighing 28–35 gm were used After killing, the muscles were removed and weighed, one of the muscles was always used as control of the other They were incubated in small vessels in a Dubnoff shaker at 37° C and stirred for 2 hr The incubation medium was 2 ml of frog-Ringer containing 3 mgm /ml glucose Contraction was elicited by incorporation of 10^{-5} *M* acetylcoline Insulin was used at a concentration of 0 1 and 0 5 mU /ml

In another series of experiments alternating 15-min periods of contraction and relaxation were induced in the same muscle, by transferring it from the buffer containing acetylcholine to the relaxation buffer and vice versa, after very careful washing and blotting on filter paper

Determinations of glucose were carried out by the Somogyi–Nelso method

The results shown in Table 1 are different from those described for mammals

(*a*) Gemmill *et al* [4,5] showed that uptake of glucose and synthesis of glycogen are stimulated in the rat diaphragm *in vitro* by the addition of insulin Our results, on the other hand, show that insulin does not increase uptake of glucose by frog muscle

(*b*) Helmreich[1] and R-Candela[2] have shown, using different experimental conditions, that muscular contraction increases the uptake of glucose sugars with a specificity similar to that found when using insulin

Table 1

	Without insulin	With insulin (0 5 U /ml)	Alternative contraction and relaxation without insulin
Contraction	0 171 ± 0 041 (20)	0 180 ± 0 047 (20)	Contraction every 15 min 0 158 ± 0 036 (20)
Relaxation	0 170 ± 0 041 (20)	0 201 ± 0 047 (20)	Relaxation every 15 min 0 148 ± 0 036 (20)

No significant differences

In the case of the frog, muscular contraction does not increase uptake of glucose

Though Gemmill[6] and Beloff-Chain[7] state that insulin does not increase oxygen consumption by mammalian muscles, Hall[8], Gourley[9], Fisher[10], Smillie and Manery[11] find that insulin increases significantly the consumption of oxygen by frog skeletal muscle

These experimental findings indicate the existence of a correlation between the effects of insulin and muscular contraction on uptake of glucose by muscle

Reversible Blocking of Nerve Conduction by Alternating-Current Excitation

In recent years, the attention of control engineers has been attracted to the communication characteristics of nerves, particularly in regard to their function in the feedback control of muscle Muscles are highly non-linear power amplifiers, which require complex nervous control circuitry to permit smooth and continuous movement of the limbs This control circuitry consists of multiple feedback loops, and the problem is to determine experimentally the function of individual loops One approach is to open circuit specific peripheral neural paths and observe the effect on over-all performance

This can be done, and problems encountered with surgical and pharmacological methods avoided, by subjecting the nerve to alternating-current excitation This method offers the advantage of reversibility, and also enables fibres to be selectively blocked according to their size An investigation has been undertaken on peripheral nerves to study the effect of alternating-current excitation on axonal conduction The sciatic nerves of large green frogs were used and a section of nerve, approximately 8 cm in length, extending from the thigh to the peroneal and tibial extensions, was supported on an array of six platinum electrodes in a bath of mineral oil (see Fig 1*a*) A pulse was applied repetitively to the stimulating electrodes and the response at the recording electrodes was amplified and displayed on an oscilloscope The centrally located blocking electrodes were excited from an audio oscillator Since the signal at the recording electrodes contained, superimposed, both the time-response of the nerve and an alternating-current component due to the ohmic coupling with the oscillator, a subtraction circuit was incorporated

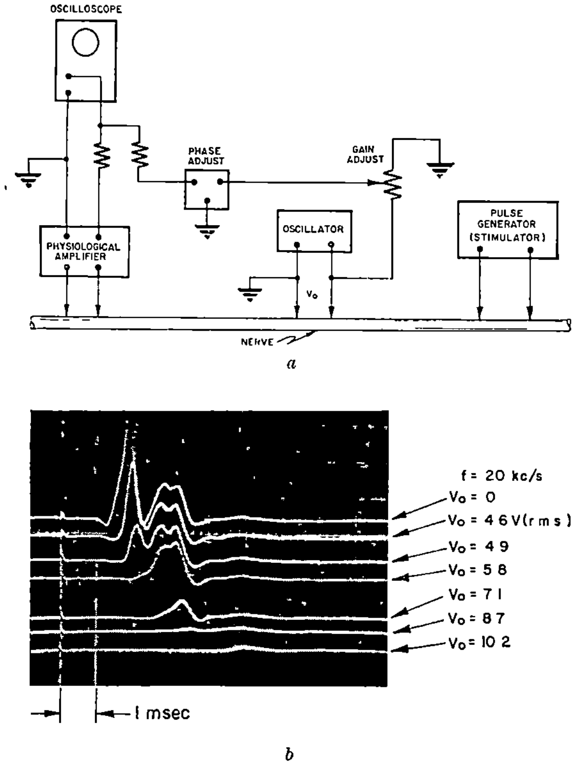

Fig. 1. *a*, Circuit arrangement for investigating reversible block of nerve conduction; *b*, characteristic compound action potential of frog sciatic nerve subjected to various levels of alternating-current excitation at 20 kc./s.

to remove the alternating-current component. A typical record is given in Fig. 1*b*, which shows the effect of various levels of alternating-current excitation at 20 kc./s. on maximal evoked α-, β- and γ-fibre responses. It will be noted that the blocking is selective, the response of the α-fibres showing considerable attenuation before any significant changes appear in the β- and γ-responses. On removal of the alternating-current excitation, the original response (corresponding to $V = 0$) is immediately restored, that is, the effect is reversible.

This experiment has also been conducted with the central portion of the nerve placed between two transversely located electrodes, in a separate bath of saline. The results were similar.

It is suggested that blocking is due to local depolarization of the nerve and that the selectivity in relation to fibre size is consistent with the membrane impedances. As a first approximation the equivalent circuit[1,2] of a membrane can be considered as a parallel combination of resistance and capacitance. The α-fibres, because of their larger surface area, have a large capacitance and a smaller resistance per unit length than the β- and γ-fibres. Therefore at any given level of alternating current excitation, the current through the large fibres would be greater than through the small fibres and the depolarizing effect would be correspondingly greater.

PHARMACOLOGY

Influence of Actinomycins on the Content of 17-Hydroxycorticosteroids in Guinea Pig Plasma

FOR some time we have been examining effects of the actinomycins in animals. For this purpose we used a pure crystalline preparation, aurantin, which contained fractions A_1, A_2, A_3 identical respectively to C_3, C_2 and C_1 fraction of the actinomycin C [1,2]. The difference between the preparations seems to be only in quantitative proportions of the aforementioned fractions[2,3]. There are indirect indications that the antibiotics of this group stimulate the function of the adrenal cortex, but there are no published results testifying to an increased concentration of corticosteroids in blood caused by the influence of actinomycins. The report here gives the results obtained in an investigation of this problem.

Male guinea pigs weighing 250–300 g have been tested. The blood was taken from the tested animals by heart puncture at a strictly definite time. For each blood-count separate groups of animals were used with six guinea pigs in each group. The free 17-hydroxycorticosteroids in the blood plasma were determined by Yudaev and Pankov's modification of Silber and Porter's method[4].

The results obtained through a single intraperitoneal aurantin injection are represented in Table 1. The *t*-test was used to evaluate the significance of the results. From these data it follows that the concentration of 17-hydroxycorticosteroids increases 1.5–2 times during 2 days after a single injection of 30 μg/kg of antibiotics. The single injection dose 75 μg/kg causes an increased concentration of 17-hydroxycorticosteroids during 7 days. Their maximum content is determined on the second day of the injection of the preparation and exceeds the control-level almost six-fold. The above doses of aurantin did not have any conspicuous toxic effect on guinea pigs at a single injection.

Table 2 shows results of investigation obtained at an intraperitoneal aurantin injection of 30 μg/kg three times a week. The blood was taken from the animals 24 h after the antibiotic injection. It can be seen from Table 2 that this increase in concentration of 17-hydroxycorticosteroids occurs 1 h after, and is observed during the whole period of the injection of the preparation and also 10 days after its termination. It should be noted that a continuous use of the preparation at this dosage caused a reduction in weight and death of some animals. With continuous aurantin injections of a non-toxic dose of 10 μg/kg the increase in concentration of 17-hydroxicorticosteroids does not begin until a fortnight after the start of investigations.

Thus, using aurantin once in a non-toxic dose of 75 μg/kg it is possible to achieve a greater effect than at a 30 μg/kg dose injection 3 times a week, though the latter injected in the way described exerts a toxic influence.

Hence, it may be supposed that reduction in the weight of the lymphoid organs observed during the injection of the antibiotics of the actinomycin group to the laboratory animals is associated with the influence of the latter on the function of adrenal cortex.

It is possible that a similar mechanism of the actinomycin action is of some importance in the therapeutic

Table 1

No	Group	Plasma concentration of 17-hydroxycorticosteroids in µg/100 ml					
		Prior to injection	1 day	2 days	4 days	7 days	12 days

Refractoriness (Tachyphylaxis) to 'Sarin'

APART from experiments reported in 1954 by Barnes and Duff[1], the occurrence of tachyphylaxis to poisons which act by inhibiting cholinesterase has been little publicized, although the phenomenon appears to offer possibilities as a means of investigating cholinergic function The following is an account of a method which, in a proportion of experiments, was found to lead to a high degree of refractoriness to 'Sarin' (isopropyl methyl phosphonofluoridate) in the cat, the conditions being those of tachyphylaxis

The anæsthetic was pentobarbital and all drugs were given intravenously (femoral vein) The median lethal dose of 'Sarin' for the cat anæsthetized in this manner is approximately 0 06 mgm /kgm, and the initial phase of the experiment consisted in the injection of about ten times this amount, the animal being protected by a combination of atropine sulphate (2–4 mgm /kgm) and pentamethonium bromide (20–40 mgm /kgm), supplemented on occasion by oxygen or artificial ventilation The antidotal drugs were given fractionally to lessen their vasodepressant action When recovery from the acute effects of the initial injection of 'Sarin' was complete, a further period of 0 5–1 5 hr was allowed to elapse and the cat was then injected with more 'Sarin' The procedure followed was to give repeated injections at 2-min intervals The early ones were extremely small (0 02 mgm /kgm each), and, as a rule, after three or four such injections a crisis developed, with a profound fall in blood pressure and virtual cessation of breathing However, on interrupting the injections rapid recovery took place, and, on resuming the injections it was found, in successful experiments, that larger and larger doses of 'Sarin' had progressively less and less effect Finally, repeated doses as large as 10 mgm / kgm each have been given, and cats have survived amounts totalling 50–200 times a lethal dose of 'Sarin', after allowing for the 10-fold protection to be expected from the antagonist drugs given One animal permitted to regain consciousness was retested one week later and found normally susceptible to 'Sarin', which indicates that the condition is temporary only

The nature of the physiological or biochemical changes in the animal associated with refractoriness has not been examined

HISTOCHEMISTRY

Histochemical Demonstration of 6-Phosphogluconate Dehydrogenase in Proliferating and Malignant Cells

IN a series of histochemical studies on tissues of the human and of rats and mice, the activity of the enzyme 6-phosphogluconate dehydrogenase was found to be remarkably increased in proliferating cells, whether they were benign or malignant This enzyme is part of the respiratory mechanism known as the pentose pathway, or 'shunt', which may provide an alternative glycolytic pathway from glucose to pyruvate it may also be implicated in the synthesis of the nucleic acids[1] Because of the possible significance of the results obtained in diverse experiments during the past two years, it was considered advisable to communicate these preliminary findings

Pieces of fresh tissue, about 5 mm^3, were chilled by being pressed lightly against the inside of a glass tube (3 in × 1 in) which had been cooled overnight in solid carbon dioxide ('Cardice') in a Dewar flask The tube was recorked and replaced, as quickly as possible, in contact with the solid carbon dioxide in the flask Sections were cut at 8 or 12μ on a refrigerated microtome, maintained at about −25° C, and they were mounted on glass slides The sections were removed from the refrigerated cabinet and were covered with the appropriate warm incubation medium The complete fluid was prepared as follows neotetrazolium (Universal Crop Protection, Ltd) was dissolved in warm 0 05 M phosphate buffer at *p*H 7 8, at a concentration of 1 mg per ml To a few millilitres of the filtered solution was added triphosphopyridine nucleotide (TPN, 5 mg/ml) and this solution was saturated with barium phosphogluconate Serial sections were treated with a similar incubation medium which lacked either the TPN or the phosphogluconate The sections were incubated in a moist chamber at 37° C for 2 h A positive result was recorded only for those areas of the section which showed a significant deposit of the formazan with the complete medium, but a negligible deposition when incubated in the media which lacked either substrate or TPN

Normal rat liver showed only very slight or even no staining by this method This was surprising, since it was known[1] that appreciable activity had been detected, by biochemical procedures, in this tissue Thus it would appear either that the method, as described, is insufficiently sensitive, or that the substrate cannot penetrate to the site of the enzyme in these sections in which the integrity of the cytological structure is well preserved[2] That the latter is the likely explanation is indicated by the finding that the livers of rats treated with ether or chloroform become stained fairly strongly by this procedure very shortly after the animal has been subjected to these anæsthetics[3] Hence in these studies it was necessary to kill the rats and mice with nitrogen This effect of increasing the penetration of the substrate might be rather analogous at the subcellular level to the inability of 6-phosphogluconate or TPN to penetrate the membrane of the human erythrocyte Thus these cells, when tested by a spectrophotometric biochemical method[4], showed no activity in the presence of this substrate and TPN On the other hand, definite activity was observed immediately after the addition of a saponin, which assumably disrupted the membrane and liberated the enzyme

The first studies were concerned with the respiratory changes that occur during carcinogenesis in the liver of rats fed with 4-dimethylaminoazobenzene (DMAB) A marked increase in the phosphogluconate dehydrogenase activity was found in the liver of rats fed with the basal diet which Elson[5] recommended for facilitating the induction of tumours (diet *C*) In all these experiments this diet was reinforced by the thrice weekly addition of about 20 g of cabbage for each rat, rats fed with this did not produce tumours, although a high yield was obtained when it was supplemented with 0 06 per cent DMAB Examination of such livers showed that both regenerating and neoplastic areas gave high levels of enzyme activity In some cases well-differentiated tumours are difficult to distinguish from regenerating livers Hence, as an additional precaution, the enzyme levels of secondary growths in the diaphragm and lung were studied, the activity of this enzyme was found to be very high in these growths On the other hand, negligible staining was observed in those areas which showed abnormal histological architecture and which, but for the apparent paucity of mitoses, might have been considered malignant In other studies on mice, a similar stimulation of the phosphogluconate dehydrogenase activity by this diet was observed in the liver, the bronchial epithelium was also responsive to this reaction, the degree varying apparently directly with the amount of hyperplasia detected In a third investigation, on human lung cancers, marked staining of the growing areas of both squamous and oat cell cancers has been seen in the relatively few cases investigated Normal bronchial epithelium contrasted strongly with adjacent neoplastic tissue and could be easily distinguished on this reaction alone

It is necessary to assess the significance of these results, and thus the limitations as well as the advantages of the histochemical procedure Clearly it is only by such methods that the biochemistry of relatively few active cells, such as may comprise small metastases, can be investigated However, it is invariably more satisfactory if the histochemical technique has been tested against biochemical estimations in such circumstances as this may be feasible, and the validity of the histochemistry so established At present this has not been done, facilities for effecting this have only recently become available On the other hand, these histochemical findings have a certain significance in that it has been shown that for this reaction to occur in the actively proliferating tissue studied it is essential to have both phosphogluconate and TPN present in the incubation medium Thus these results may be of interest in indicating a probable stimulation of phosphogluconate dehydrogenase in cellular proliferation and particularly in neoplastic growth Moreover, the findings from the experiment on the effect of the altered diet suggest that tissues may become predisposed towards an enzymatic situation which is characteristic of proliferation

Intracellular Mucus in the Human Bronchial Tree

A FURTHER step in the investigation of the composition of mucus in chronic bronchitis and other pulmonary diseases has been made possible by the use of combined histochemical and enzyme digestion methods to characterize epithelial mucus-secreting cells

An important component is acid mucopolysaccharide which can be detected by its staining blue in a combined alcian blue/periodic acid–Schiff stain (AB/PAS)[1] Two types of acid mucopolysaccharide can be traced If two consecutive sections are stained by AB/PAS, one after digestion with neuraminidase, the site of neuraminidase-susceptible neuraminic acid is indicated by the elimination of blue staining[2] The other accepted source of acid in mucopolysaccharide—sulphate—has been traced by Pelc's method of autoradiography–sulphur-35 as sulphate, given intraperitoneally to mice and rats, the animals being killed up to 2 hr after injections of 8 μc /kgm body-weight in human bronchi, by tissue culture of bronchial biopsy material in medium to which labelled sulphate has been added

In the mouse, surface epithelium and glands show no sulphate uptake, all acid mucopolysaccharide being susceptible In the rat a regional variation not previously described has been found (1) in peripheral airways no uptake of sulphate occurs, any acid mucopolysaccharide being neuraminidase-susceptible, (2) in the trachea most (but not all) cells containing acid mucopolysaccharide take up sulphate[3], none being susceptible to neuraminidase, (3) in the large bronchi of the hilar region both types of acid mucopolysaccharide are found

After 1 hr in the culture medium uptake of sulphate by the human bronchus is found only in acini which are granular, there is uptake of sulphate in an occasional distended cell of the surface epithelium and also in cells which do not stain for mucopolysaccharide after tissue culture, but probably represent granular cells That these sulphated cells stain poorly may be an example of the irregular staining with alcian blue by known sulphated compounds[4]

The finding of acid mucopolysaccharide in human bronchus is thus independent of any uptake of sulphate except for the occasional cell mentioned above Granule-containing ('granular') cells as well as those distended with secretions ('distended' cells) are both found in surface epithelium, duct and gland acini Generally, granules show the same range of staining characteristics as distended cells, and with the AB/PAS method both types include blue-, purple- and red-staining cells, while after sialidase-digestion cells of the same colours are seen but in different proportions Epithelial mucopolysaccharides have been isolated which contain a large proportion of neuraminidase-resistant neuraminic acid[5,6] Sialidase converts some blue cells to purple, some blue to red and some purple to red, that is, some blue and purple cells contain an acid mucopolysaccharide which is completely susceptible to sialidase, but others contain mucopolysaccharide resistant to this enzyme although no uptake of sulphate is seen The significance of purple-staining cytoplasm is not clear, it may represent a lesser concentration of acid mucopolysaccharide than does the blue, but it may also be due to acidic groups other than neuraminic acid or sulphate Evidence can be offered for each of these hypotheses

These resistant blue cells are relatively more numerous on the surface and in ducts than in the glands As the volume of the glands is much greater than that of the goblet cells[7] it may be that these surface cells contribute so small a fraction to total secretion that this has not been detected *in vitro*

HISTOLOGY

Dermal Elastin in Actinic Elastosis and Pseudoxanthoma Elasticum

FOR sixty-five years the identity of the fibres staining with elastic tissue stains in actinic (senile) elastosis has been the subject of debate[1–5] Recent work has shown that elastotic dermis contains more hexosamine and less hydroxyproline than covered skin and that these changes are localized in the upper dermis[6] This communication describes the estimation of elastin from elastotic skin determined after extraction in hot alkali[7]

Chronically sun-damaged skin (actinic elastosis) was obtained from three human volunteers Skin from one individual with pseudoxanthoma elasticum was obtained at necropsy The presence of increased elastic tissue staining was confirmed histologically in all cases Skin of the abdomen from necropsied adult humans was used as controls, only the upper 0 3 mm elastotic and control skin were used corresponding to the localization of the staining abnormality The entire thickness of defatted pseudoxanthoma elasticum skin was used The epidermis was heat separated and the dry weight of dermis obtained Dermis was minced in a high-speed homogenizer and extracted for 15 min four times in 0 1 *N* sodium hydroxide in a boiling water bath The suspension was centrifuged at 20,000*g* and the residue hydrolysed overnight in sealed tubes at 100° C with 4 *N* hydrochloric acid Hydroxyproline and Kjeldahl nitrogen determinations were performed on aliquots Elastin content was calculated by multiplication of the hydroxyproline by 62 5, the nitrogen by 5 78, based on hydroxyproline content of 1 6 per cent and nitrogen of 17 3 per cent[8,9]

Table 1 gives the results expressed as mgm elastin/100 mgm dry weight dermis, based on hydroxyproline content The mean of the ten controls was 2 41 ± 0 7 In contrast, elastotic dermis contained 8 02, 13 08 and 10 45 mgm elastin and dermis from one individual with pseudoxanthoma elasticum had an elastin content of 6 34 mgm It should be noted that, based on the nitrogen content of the alkali-insoluble residue, the elastin content would be even higher for the elastotic specimens

The method of preparation of these fractions and their hydroxyproline content suggest that the increased elastic tissue staining seen in histological sec-

IMMUNOLOGY

Recovery of Thyroid Antibodies from Human Thyroid Preparations sensitized *in vitro*

THE development of circulating autoantibodies to thyroglobulin in some forms of experimentally produced animal thyroiditis or in chronic human thyroiditis has been described[1]

A method for isolating the thyroid antibodies in relatively pure form is of value for serological and physicochemical studies A convenient method for recovery of blood group antibodies from the powder of erythrocyte stroma was previously described[2] A somewhat similar procedure was used in the present work to obtain 'pure' thyroid autoantibodies from sera of patients suffering from chronic thyroiditis, and thyroid heteroantibodies from sera of rabbits injected with human thyroid extract

Human thyroid gland was ground in a Waring blender, spread in a thin layer in Petri dishes, and dried at 37° C The preparation was gently scraped off with a razor blade, and the fine thyroid powder was obtained

Table 1 REACTIONS OF ANTI-THYROID SERA AND ELUATES OBTAINED FROM SENSITIZED HUMAN THYROID POWDER

		Tanned cell hæmagglutination, highest dilution of the specimen tested giving marked reaction with human red blood cells coated by human thyroid extract		Complement fixation test, highest dilution of 50 per cent human thyroid extract giving marked reaction with the specimen tested	
		Whole serum	Eluate	Whole serum	Eluate
Rabbit anti-human thyroid serum	No 775	2,187	243	65,610	21,870
Rabbit anti-human thyroglobulin serum	No 767	6,561	729	65,610	21,870
	No 766	59,049	6,561		
Human thyroiditis serum	War	2,187	243	< 90	< 90
	Swi	2,187	243	< 90	< 90

As expected, the suspension of thyroid powder reacted strongly in complement fixation tests with rabbit antisera against human thyroid and human thyroglobulin On washing, the thyroid powder released a potent soluble antigenic material, presumably thyroglobulin, which could be demonstrated in supernatants from at least six consecutive washings

When the suspension of thyroid powder was heated for 30 min at 100° C its antigenic activity was not influenced at all, a finding which was not surprising in view of the thermostability of thyroglobulin[3] However, washing fluids of heated powder were apparently devoid of any *in vitro* serological activity It seemed conceivable that heat coagulation of the surrounding protein material might have bound thyroglobulin to the thyroid particles

A fine suspension of thyroid powder was prepared by vigorous shaking of 0 2 gm of the powder in 10 ml of saline Some experiments were performed with unaltered preparations, whereas for others, the suspension was heated for 30 min at 100° C The powder was washed at least three times with saline To 0 4 ml of washed sediment was added 1 ml of undiluted human serum from patients suffering from chronic thyroiditis or rabbit antiserum against human thyroid The tubes were shaken for 2 hr on an electric shaker Parallel experiments were performed at 4°, 23° and 37° C The sensitized powder was washed at the temperature of sensitization for at least four times and resuspended in 0 5 ml of saline In the fourth washing fluid of sensitized thyroid powder no thyroid antibodies, or only traces of them, could be detected Then the tubes were shaken for 5 min in a water bath at 56° C , and centrifuged for 5 min at 3,000 r p m in a heated centrifuge at a constant temperature of 56° C After centrifugation, the eluates were withdrawn as quickly as possible

Eluates from unheated thyroid powder did not react in tanned cell haemagglutination and complement fixation tests with human thyroid extract This finding may be attributed to the release from the unheated powder of active antigenic material which probably neutralized most of the antibodies Anticomplementariness found in eluates of thyroid antibody of rabbit origin might have indicated the presence of soluble antigen–antibody complexes

As is to be seen in Table 1, eluates from heated thyroid powder contained thyroid antibodies, rabbit antibodies were active in tanned cell hæmagglutination and complement fixation tests, human antibodies were active in tanned cell hæmagglutination tests only (as were the original thyroiditis sera) The activity of eluates apparently did not depend upon the temperature of sensitization, preparations obtained from thyroid powder sensitized at 4°, 23°, and 37° C were equally potent Eluates from similarly treated powder of human organs other than thyroid did not contain thyroid antibodies Serological reactions with eluates of thyroid antibodies were weaker than the reactions with the corresponding original sera

The first elution was never complete and two to three consecutive eluates still showed marked antibody activity Antibodies against human serum proteins present in rabbit anti-human thyroid sera were reduced to traces in eluates

The eluates of human thyroid autoantibody effectively inhibited the activity of rabbit anti-human γ-globulin serum in bringing about the agglutination of Rh^+ red blood cells sensitized by incomplete Rh antibody In addition, sera of two rabbits immunized intravenously with these eluates acted as potent Coombs reagents These experiments established the fact that eluates contained γ-globulin

If desired, the eluates of thyroid antibodies might be concentrated by freeze-drying or evaporation and further properties of the tissue-reactive antibodies studied

Transfer of Nephrotoxic Glomerulonephritis in Rats by means of White Blood Cells

Transfer of experimental glomerulonephritis on originally healthy rats has been accomplished in this and other laboratories by means of parabiosis[1,2] Transfer was observed in random-bred as well as in inbred rats, either in short-term experiments or after intervals up to 71 days between institution of nephrotoxic serum glomerulonephritis in the primarily nephritic animal, and parabiotic conjunction with the originally healthy partner[3–5] Fluorescein-labelled antisera were used to exclude the involvement of the primarily injected heterologous (rabbit) antibodies in the transfer phenomenon[6] From these experiments it was derived that a secondary nephritis-producing factor, appearing as a consequence of the nephrotoxic serum glomerulonephritis in the circulation of the primarily nephritic rat, was transferred to the primarily healthy animal capable of attacking the corresponding organs of the latter

This conclusion was supported by recent experiments which were an attempt to localize the transfer factor in question First, the parabiosis was substituted by continuous cross-transfusion (that is, bilateral carotid artery-jugular vein anastomosis), and glomerulonephritis was transferred on 5 out of 15 healthy rats following cross-circulation of 2 5–4 days duration[7] Secondly, plasma and white blood cells from nephritic rats were injected (for 4–15 days) or infused (by using a modification of the technique of Armin *et al* [8] for continuous infusion of solutions in unanæsthetized animals) into healthy recipients As in the former experiments, a highly inbred strain of Sprague–Dawley rats was used consistently Development of experimental glomerulonephritis was observed in 5 out of 31 recipients following transfer of 210–450 million white blood cells from 4–10 nephritic donors, only in 1 out of 32 animals receiving 10–35 ml of plasma from the same donors, the controls, 52 recipients of plasma and white blood cells from healthy donors, being completely negative

Since in rats 75–80 per cent of the white blood cells are lymphocytes and transfer of experimental 'autoimmune-nephrosis' on immunologically tolerant rats recently was achieved by injecting lymph node cells[9], the results reported herewith are in favour of a lymphocyte-bound nature of the secondary nephritis-producing factor in nephrotoxic serum glomerulonephritis likewise in rats In contrast to the transfer of an autoimmune-nephrosis, however, Freund's adjuvants was not used in our experiments They suggest, on the other hand, the induction of an autologous hypersensitivity reaction of the delayed type following a passive heterologous anaphylaxis in the glomeruli Possibly this secondary mechanism is responsible for the progression of the disease, once it has started Further work is required for elucidating the immunological nature of the secondary nephritis-producing factor in question

BIOLOGY

Significance of Mitotic Duration in evaluating Kinetics of Cellular Proliferation

Mitotic rate or 'rate of cell renewal' can be defined as the number of cells which complete their mitosis per unit time

$$\text{Mitotic rate} = \frac{\text{mitotic count}}{\text{mitotic duration}}.$$

As can be seen from this equation, and as also emphasized by Leblond and Walker[1], mitotic count can be used to estimate mitotic rate only if mitotic duration is not significantly influenced by the experimental conditions

The literature on kinetics of cellular proliferation seems to display an agreement concerning the time for synthesizing DNA (S) and the mitotic duration (M) which are assumed to remain relatively constant even during periods with changing rates of cell renewal The intermitotic 'resting period' (G_1) is, on the other hand, supposed to change parallel to the changes in growth-rate of the tissues under examination This has led to the assumption that mitotic count and number of cell nuclei which are labelled with a radioactive DNA precursor can be used synonymously with mitotic rate and rate of DNA synthesis The correctness of this assumption may be doubted after the following investigations, which demonstrate experimentally induced changes of mitotic duration

By the colcemid technique the mitotic duration of the epidermal cells of 'normal' hairless mice has been estimated to about 1 hr , and the average mitotic count has been found to be 0 57 per cent The animals were killed between 9 and 10 a m

The estimation of the DNA synthesizing time was made by using repeated injections of tritiated thymidine with subsequent autoradiography, and the rate of DNA synthesis was analogously calculated from the number of labelled cell nuclei and the DNA synthesizing time The DNA synthesizing time is thus found to be about 5 3 hr and the rate of DNA synthesis to 0 55 per cent per hour between 9 and 10 a m

In a previous paper[2] it has been shown that the mitotic count and the number of DNA synthesizing cells in the epidermis of hairless mice decreased during the first two days after application of 0 005 ml of 1 per cent 3 methylcholanthrene in benzene A very short initial increase in the mitotic count has been shown to be due to blocking of the mitoses[3] After the first two days an increase both in mitotic count and in number of DNA synthesizing cells was observed The values reached a peak on the 11th day after the application of methylcholanthrene, and then fell slowly for the next four weeks

After application of different carcinogens to the epidermis of these animals, it was observed, in subsequent experiments, that the mitotic duration and the DNA synthesizing time as well as the mitotic rate and the rate of DNA synthesis vary considerably The experiments show that the rate of mitoses and of DNA synthesis roughly parallel each other, and are increased about three times 24 hr after the application of methylcholanthrene The mitotic duration and the DNA synthesizing time are at the same time decreased to a quarter of normal values The mitotic count is markedly increased eleven days after the application of methylcholanthrene The mitotic rate, however, is only slightly above the rate in untreated epidermis, and the mitotic duration is increased to about 2 hr

It has thus been demonstrated that the application of certain skin carcinogens to mouse epidermis heavily affects the mitotic duration and the DNA synthesizing time Previous calculations of the rate of cell renewal directly by mitotic counts after application of carcinogens are thus open for re-evaluation

Leptospira Infection in the Gold Fish (*Carassius auratus*)

THE important role of waterholes, rice fields, swamps slow-moving streams and sewers in the epidemiology of human and animal leptospirosis has been established[1-3] Wild animals and migratory birds, present in surrounding areas, have been found to be infected and have been implicated in the dissemination of the disease[4-7] On the other hand, little is known about the role of strictly aquatic forms such as fish, or of partially aquatic forms such as amphibians Negative results have been obtained in isolation attempts from minnows[8] and amphibians[5], equivocal findings have been reported in frogs[9,10], leptospiral antibodies have been found in water turtles[11,12]

The ability of *Leptospira* to penetrate the bodies of fish living in contaminated water has been determined in the experiments reported here, the course of the infection in the host's tissues has been followed

Goldfish (*Carassius auratus*) 5 cm long, free from infection, were used They were maintained in tap water which was contaminated with 7-day-old cultures of *L pomona* and *L canicola* The concentration of micro-organisms was determined by subculturing serial ten-fold dilutions in semi-solid Fletcher's medium containing 10 per cent rabbit serum The water was aerated and the temperature regulated at 18°–20° C The fish were fed twice daily The original *p*H of the water was 5, but before contamination it was raised to neutrality by addition of 10 per cent sodium bicarbonate solution

Dark field microscopy and fluorescent antibody procedure were utilized in the detection of micro-organisms in the sediment obtained by high-speed centrifugation of water samples Cultures of water in semi-solid Fletcher's medium were made in the first experiment only

The search for *Leptospira* in fish was made by cultural means (the seeding of about 0 05 ml of brain, heart, kidney and muscle tissues collected and shredded aseptically by means of a capillary pipette) and by means of fluorescent antibody procedure applied both to smears and to frozen tissue sections Cultures were submitted every second week for six weeks to dark-field microscopy and in case of contamination or of negative results, a drop was smeared on a slide and 'stained' with the fluorescent antibody technique

Methods used in the preparation of immune sera, fluorescent conjugates, sorption, collection and sectioning of tissues, and microscopic observation have been reported earlier[13] Anti-*L pomona* and *L canicola* conjugates were used in the first and second experiment, respectively They intensely stained smears made from cultures of *L icterohaemorragiae*, *L canicola* and *L pomona*, and did not stain *L biflexa* Sorption of the conjugates with dog liver, chicken embryo, and trout muscle extracts gave satisfactory results The smears and sections were fixed for 5 min in acetone They were then dried and washed in buffered saline for 10 min before applying the conjugate This was left in contact with the experimental material for 1 hr at room temperature before washing and mounting with buffered glycerin

Specificity of the fluorescent antibody procedure was tested on materials not containing *Leptospira*, materials containing *Leptospira*, and by inhibitions of staining by application of anti-*Leptospira* immune, non-labelled globulin before use of the fluorescein-labelled globulin.

In a preliminary experiment carried out for orientation purposes fish were introduced into a tank of contaminated water of *p*H 7.2 containing 50 *L. pomona* per ml. At 1 hr., 4 hr. and 1, 2 and 8 days, 20 ml. samples of water and two fish were collected and examined for the presence of *Leptospira*.

The micro-organisms were demonstrable in the water by means of dark-field microscopy for 24 hr., and by means of the fluorescent antibody procedure for 8 days following contamination. *Leptospira* were present in the gills, liver and muscle of the fish from 1 hr. after contamination to 8 days, the end of the experiment. The gills appeared to be the site of highest concentration of *Leptospira*, liver and muscle were next highest in that order. In the muscle, limited numbers of *Leptospira* were present in the blood vessels, while in the liver, on the eighth day, they were also present in the parenchyma.

A second experiment was extended over a longer period of time (17 days) and a higher number of *Leptospira* were present in the water (800,000 *L. canicola* per ml.). After being kept in the contaminated water for 24 hr., fish were transferred to clean water of *p*H 5. This passage was frequently repeated during the course of the experiment in order to eliminate the possibility of a super-infection.

A water sample and one fish were collected at intervals for a period of 17 days. Cultures were made from brain, heart, liver, kidneys and abdominal muscles of the fish. *Leptospira* were visible in the water by means of dark-field microscopy and fluorescent antibody 'staining' for 24 hr. after contamination, but never in the samples collected at a later time. Cultures obtained from brain, heart and muscle of the fish were positive from 1 hr. to the tenth day, while cultures from the kidneys were positive from the second to the seventeenth day. Fluorescent antibody 'staining' demonstrated the presence of the infection in the gills and the liver at 1 hr., in the muscle at 24 hr., in the kidney at 48 hr., and persistence of the infection in all tissues to the seventeenth day. The highest concentration of *Leptospira* was found on the surface and the tissues of the gills. High concentrations were also present in the hepatic parenchyma from the third to the eighth day, and in the kidney from the eighth to the seventeenth day.

It seems to be obvious that *Leptospira* can penetrate into goldfish through the gills because only sections of this tissue and not of intestine and of skin showed the presence of micro-organisms at the beginning of the experiment. A large volume of water is constantly circulating through the gills, and fine particles can be mechanically detained there, for example, *Leptospira*, yeasts, bacteria and amorphous debris. *Leptospira* can then apparently find their way into the blood-stream and spread throughout the animal's tissues.

Results obtained through the application of cultural and fluorescent antibody procedures were similar. In a large number of contaminated cultures, the fluorescent antibody procedure detected the presence of the *Leptospira* where dark-field microscopy had given negative results.

Goldfish are susceptible to *Leptospira* infection when living in contaminated water and also appear to harbour these organisms for at least 17 days even when living in water with a *p*H which is lethal to the organism. No serological or histopathological work was performed, and thus no evaluation made on the immunological and tissue responses of the host to the infection. The gills and kidneys seem to be the major site of localization of the *Leptospira* after the septicæmic stage, suggesting the possibility of shedding micro-organisms into the surrounding water.

The aforementioned results, although obtained from the study of few individuals, strongly support the possibility of fish occupying an important role in the epidemiology of *Leptospira* infection in certain environments. The results also indicate that an investigation of aquatic animals in endemic areas might yield useful information.

Sexual Differentiation of Merozoites of *Barrouxia schneideri* (Butschli)

SCHELLACK[1] in a study of Coccidia from *Lithobius* and *Scolopendra* recognized the presence of more than one type of merozoite in *Barrouxia schneideri*. He nevertheless concluded they did not represent sexually dimorphic forms. In recent cytochemical investigations of the same parasite two types of merozoite were recognized, which differed in the amount of carbohydrate reserve stored in the cytoplasm and in nuclear structure. Using the periodic acid–Schiff test, some bundles of merozoites were shown to have no carbohydrate reserves other than a few fine granules. These correspond to the microgametocytes which have sparse reserves of fine, discrete granules occupying the central cytoplasm. Other merozoites, often shorter and broader in form, have considerable reserves already in the form of large granules merging together. There is no difficulty in tracing a series of developmental stages between these and the macrogametocytes with their abundant carbohydrate reserves. Furthermore nuclear differences existing between the two types of merozoite can be traced to the gametocytes. The conspicuous polar nucleolus of the 'female' merozoite persists throughout the development of the macrogametocyte. A nucleolus is absent from the nuclei of the 'male' merozoite and the micro-gametocyte.

Such a demonstration of what is highly probably sexual dimorphism in the merozoites of *Barrouxia*, again raises the question if two sexes exist throughout the entire life-cycle as a general rule in the Coccidia. We know from the work of Dobell and Jameson[2] on *Aggregata eberthi* that the reduction division occurs, not during gametogenesis but in the first division of the zygote, so that the parasite is haploid. This is now accepted as universal in the Coccidia. Furthermore, from Tyzzer's demonstration[3] that a patent infection with *Eimeria maxima* can be achieved with a single sporulated oocyst we know that the zygote carries the characters of both sexes. This is now a routine method of producing pure-line infections of Coccidia. Sexual differentiation occurs at some point between the diploid, bisexual zygote and the haploid macro- and micro-gametocytes.

If sex determination is genotypic the male and female characters must be separated at nuclear division either during schizogony or sporogony. If separation of the sex characters occurred at zygotic meiosis the resulting sporocysts would be unisexual, male or female, and it would not be possible to produce a patent infection with a single sporocyst. If separation occurred at nuclear division within the sporocyst both male and female sporozoites would be enclosed within the sporocyst, which would then be sufficient to establish an infection resulting in oocyst production. If separation occurs only at schizogony the sporozoites must be bisexual and a single sporozoite would be sufficient to establish a patent infection.

The existence of two sexually differentiated types of merozoite and the inability of a single sporocyst to produce both sexes would indicate zygotic meiosis as the point of sex separation. Reyer[4] was unable to obtain a patent infection of *Barrouxia schneideri* using a single sporocyst but could do so with a single oocyst. Though he unfortunately did not establish if the sporocyst resulted in the production of one type of gametocyte his results, together with the present demonstration of the existence of two types of merozoite, is strongly indicative that the reduction division is the point of sexual differentiation.

Single sporocyst and single sporozoite infections are being attempted with *Eimeria tenella* to ascertain the sex of the bodies resulting. If either all male or all female infections can result from inoculation of a single sporozoite, phenotypic sex determination is ruled out.

Discharge of Marrow Eosinophils following Re-injection of Foreign Protein

In an earlier investigation[1], using the quantitative methods developed in this laboratory[2], it was shown that very large reserves of mature and nearly mature eosinophils are present in the bone marrow of normal guinea pigs. The question arose as to the circumstances in which these cells might be discharged, and for this reason it seemed important to carry out a quantitative investigation during the circulatory eosinophilia which follows the re-injection of foreign protein in sensitized animals. Percentage changes in bone marrow eosinophils have been noted in these conditions[3].

Preliminary experiments showed that a high blood eosinophil-level was present in guinea pigs, 24–30 hr. after the last of 4 subcutaneous injections of horse serum at 5-day intervals; when the fourth injection was replaced by saline or egg albumen, a much lower level was found. In the main series, three groups, each containing 10 healthy male guinea pigs of the Mill Hill strain, were examined; the final body-weight of each animal was approximately 400 gm. Four sterile subcutaneous injections of 1 ml. volume were administered at 5-day intervals. Group *A* received saline on each occasion. Group *B* received horse serum for the first 3 and saline for the fourth injection. In Group *C*, all 4 injections were of horse serum. To make the groups comparable with others still under investigation, each animal also received subcutaneous injections of saline at 1, 9 and 24 hr. after the fourth injection; at 29 hr. the animal was killed and the numbers of eosinophils per $mm.^3$ of blood and bone marrow determined by methods essentially similar to those reported earlier[1].

The average counts of eosinophils per $mm.^3$ of blood ($\pm$ *S.D.*) were: group *A*, 71 ± 65; *B*, 150 ± 68; *C*, 976 ± 443. In group *A*, the average number of eosinophils per $mm.^3$ of marrow (76,500 ± 15,500) was similar to normal[1]. The average number in group *B* (128,000 ± 39,200) was about 70 per cent higher and this increase was largely the result of an increase in the marrow reserves of band and segmented eosinophils; this can be interpreted as being the result of a proliferation of the eosinophil series following the last foreign protein injection some 6 days before. The average number of eosinophils in group *C* (74,300 ± 36,000 per $mm.^3$) was 42 per cent less than in *B*, and again, mature and nearly mature forms were largely responsible for the difference. As there was no evidence of increased destruction or phagocytosis of eosinophils in the marrow, this difference may give a measure of the number of extra eosinophils discharged into the circulation of group *C* in the 29 hr. following the re-injection of specific antigen. (All the differences mentioned were significant at the 0·01-level of probability.)

By using quantitative data already obtained for bone marrow volume[4] and blood volume in the 400-gm. guinea pig, one can make very approximate calculations of the total numbers of eosinophils involved[1]. It would appear that on average about 340×10^6 band and segmented eosinophils had been discharged from the marrow reserves of group *C* but that less than 10 per cent of this total was present in the blood-stream. One may presume that more than 90 per cent had already left the circulation.

It would seem that quantitative studies of similar design might be utilized to throw light on other factors influencing the release of eosinophil leucocytes from the bone marrow.

Triops granarius (Lucas) (Crustacea) as a Natural Enemy of Mosquito Larvæ

LITERATURE on the natural enemies of mosquitoes reviewed by Hinman[1-3], contains little to suggest that crustaceans are of much significance as biological control agents. Therefore, and in view of the fact that there is renewed interest in biotic factors in vector control[4], this communication may stimulate others to pursue the matter further than I can.

El Bur (4° 41′ N., 46° 36′ E.) in the Mudugh plain of central-northern Somalia is a village of about 300 huts placed on a small elevation above a depression in which some shallow wells have been dug. The climate is typical of the region with a total of about 10 in. rain falling during April–May (*gu* rains) and September–November (*der* rains).

In 1956 El Bur was visited by the Somalia National Malaria Service during the *gu* rains when 15–20 adult *Anopheles gambiae* per room were caught by hand. An attempt to find larvæ either in the wells or in a large shallow depression which had filled with rain water, however, was unsuccessful. This was the more puzzling since no other water suitable as breeding places was anywhere to be found.

During this search it was noted that the water along the whole fringe of the depression was swarming with a large crustacean later kindly identified for me by Mr. Longhurst of the British Museum as *Triops granarius* (Lucas) (Fig. 1). It seemed that the presence of this crustacean corresponded with the absence of larvæ and this was afterwards confirmed by numerous other observations in Mudugh and Mijustinia during 1956–59, as, for example, at the villages of Adado, 1956–57, Sinadogo 1957, El Bur 1957–59, Mataban 1957, Salahdadab 1957, Goffafo 1957, Mirrich 1957–59 (Maffi 1960)[5]. In Sinadogo, Mirrich and Adado it was particularly noticeable that those wells which had mosquito larvæ contained no *Triops*. Such wells were separated by only a few metres from wells with *Triops* and no mosquito larvæ.

At no time were *Triops* actually caught in the act of catching or devouring mosquito larvæ, but the possibility that they do so or in some way make the water unattractive or uninhabitable for mosquito larvæ cannot be dismissed.

Longhurst[6] indicates that *Triops* usually occur in temporary pools and that the eggs show great powers of resisting desiccation. In Somalia, *Triops* are mostly found in exposed shallow collections of still and muddy water without vertical vegetation and in shallow wells, its habitats thus presenting conditions highly favourable for *A. gambiae*.

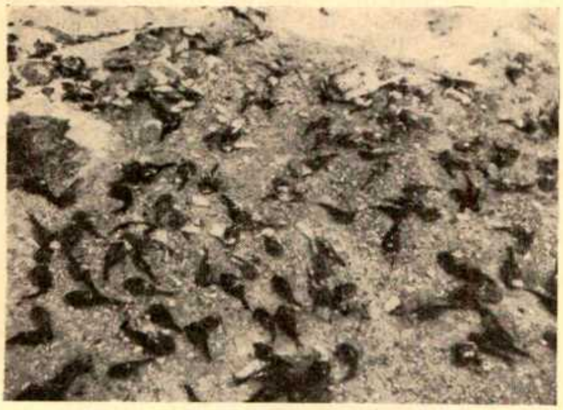

Fig. 1. *Triops granarius* along the margin of a shallow pool at El Bur, Somalia, 1956

Though the evidence is far from conclusive it is obvious that the matter merits further study. The particular characteristics of *Triops* which are of interest to the sanitarian are, of course, the ability of the eggs to withstand desiccation and the preferential breeding places which coincide so nicely with those of *Anopheles gambiae*.

Maturation of Schistosome Eggs *in vitro*

EGG-LAYING *in vitro* by *Schistosoma japonicum* and *S. mansoni* in serum media was not described by early investigators[1-4], and presumably did not occur. Later it was reported that a few eggs were laid when flukes were kept for up to two months in a glass apparatus with provision for daily change of medium (horse serum)[5]. A method of maintaining *S. mansoni* flukes so that a regular output of 30–40 eggs a day was obtained has recently been published[6-8]. Some cell division was seen, but the eggs did not mature in serum media, saline or Tyrode's solution.

During experiments in which *S. mansoni* pairs were kept in whole blood continuously dialysed against serum, some mature eggs were found after 15 days, and a few hatched out apparently normal miracidia. After further investigation, it became clear that the presence of blood cells assisted maturation and that eggs were laid and would mature in medium consisting of one part of serum, two parts of Tyrode's solution and a small addition of red and white cells; dialysis of the medium was not necessary. Attempts were then made to obtain enough miracidia to infect snails.

Paired *S. japonicum* and *S. mansoni* flukes were removed from portal veins of infected hamsters and placed in Carrel flasks containing 3 ml. of a guinea pig serum/Tyrode medium (1 : 2) with added glucose, streptomycin and penicillin. This had proved to be the best medium for regular egg production[8]. Five to nine days later, when eggs had been laid, the medium was changed to human serum/Tyrode with a few drops of buffy coat. Full sterile precautions were observed. Although many eggs were produced and cell-division began, none reached maturity, and the medium was clearly unsatisfactory.

In spite of the pre-eminence of guinea pig serum, it was decided to keep *japonicum* flukes in human serum/Tyrode (3 : 10) and *mansoni* flukes in baboon serum/Tyrode (3 : 10) with added glucose (2 mgm./ml.) and penicillin and streptomycin (100 units/ml.). One pair was incubated at 37° C. in each 6 in. × ¾ in. tube containing 5 ml. of medium. Tubes were opened after 14–17 days and the eggs recovered, washed well in saline and hatched in tap water in a watch glass.

Twenty to thirty miracidia were obtained from each *S. japonicum* tube and at least 30 from each *S. mansoni* tube These came from the layings during the first few days of incubation, and many more live immature eggs at all stages of development were seen Snails (*Australorbis glabratus* and *Oncomelania hupensis*) were exposed for 2 hr to approximately 10 freshly hatched miracidia per snail and penetration was seen to take place They were checked for the production of cercariæ between 4 and 11 weeks after infection and when all were found to be negative, were squashed and examined No sign of infection could be found Although the method has been successful in maturing the eggs of these two species of schistosome *in vitro*, the miracidia, the behaviour of which appeared normal in every way, were unable to develop after penetrating the snail hosts

S mansoni flukes have been cultivated *in vitro* from 7 days old to near maturity[9-10] Now that egg-laying by adults and maturation of the eggs have been achieved, only two stages of the mammalian cycle *in vitro* remain, that from cercaria to 7 day larva and from sexually immature to mature adult

Multiple Medullæ in Wool Fibres

IN the course of investigations on the fleece of Blackface sheep[1], we encountered several of the multi-medullated fibres described by Jones[2] We made no permanent record of these fibres, but they certainly occurred in samples from more than one sheep Since this time we have been examining samples from different strains of the same breed in a different locality and again have found similar fibres Out of 50 sheep in one experiment, multi-medullated fibres were found in samples from five individuals In each case the fibres occurred in samples taken in two separate years We estimate that between 1 and 5 per cent of fibres in these samples showed this characteristic at some stage in their growth A few fragments were found in which the medulla could be seen to change from single to double

Multiple medullæ are most commonly found among the fine wool fibres, derived from secondary follicles, of which about 70 per cent in this breed are medullated The type of medullation in the fine fibres varies from the uninterrupted to the fragmental grades described by Wildman[3] Whereas the multiple medulla have been commonly found in fine wool fibres of between 36 and 48μ diameter we have recently found some to occur in the coarse hair fibres associated with the primary follicles Invariably these were in the finest of the coarse fibres, ranging from 60–74μ, and almost always occurred in a region in which the normal lattice type medulla was absent We have previously regarded such fibres as developmental aberrations of unknown origin although it seems that they are more or less permanent features of their parent follicles

Occurrence of *Schoenus nigricans* L. in the Blanket Bogs of Western Ireland and North-West Scotland

THE anomalous position of the fen plant *Schoenus nigricans* in the blanket bogs of western Ireland[1,2] and north-west Scotland[2] can be explained to some degree by the extreme sensitivity of this species to aluminium ions

Growth chamber experiments have shown that concentrations of aluminium ions as low as 1 p p m will severely inhibit root elongation in *Schoenus*

The experiments described here were carried out in water culture, at 21° C , 16 hr day-length and 90 per cent relative humidity The culture solutions were replaced three times in a week The seed was collected from Lough Carra, Co Mayo The seedlings were germinated on filter paper in distilled water and used when one month old

The effect of aluminium ions on the root elongation of *Schoenus* is shown in Fig 1

The results of an experiment showing root elongation of *Schoenus* in natural blanket bog water collected

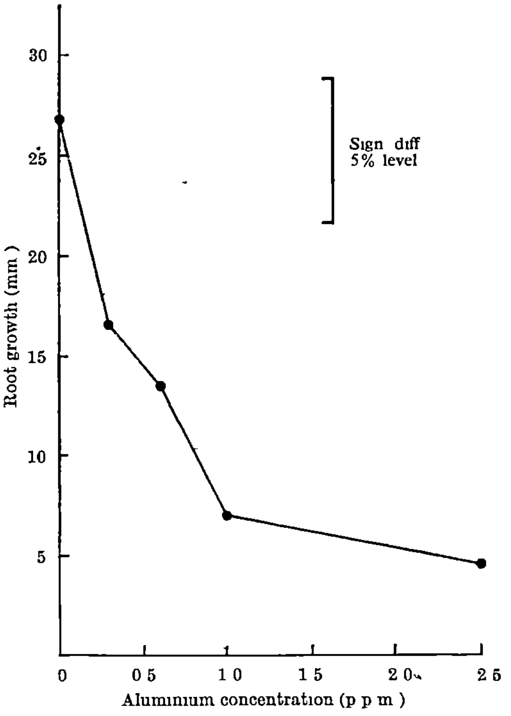

Fig 1. Root elongation of *Schoenus* seedlings at various aluminium concentrations. The ionic concentrations of other cations in solution were calcium, 15 p p m , magnesium, 9 p p m , sodium, 12 p p m , potassium, 3 p p m , iron, 1 p p m , *p*H 4 5 Duration of experiment, 42 days

Table 1

	Root elongation (mm.)	*S.E.*
Natural blanket bog water	51.1	± 7.1
With 1 p.p.m. aluminium added	12.2	± 3.7
'Synthetic' blanket bog water	48.1	± 7.9
With 1 p.p.m. aluminium added	7.6	± 2.9

Duration of experiment, 42 days

from western Ireland and that of a culture solution made up to resemble this in all major inorganic ions, are given in Table 1.

Aluminium would adversely affect the establishment and growth of the plant due to its inhibition of root growth.

The results of analyses of ombrotrophic bog waters are presented in Table 2.

Table 2. CALCIUM AND ALUMINIUM CONCENTRATIONS OF SEVERAL BOG WATERS IN THE BRITISH ISLES

Bogs with *Schoenus*	Aluminium (p.p.m.)	Calcium (p.p.m.)
Blanket bog drain, Skye	0.31	3.00
Blanket bog, Glenamoy, Co. Mayo	0.03	1.26
Blanket bog, Sheskin Lodge, Co. Mayo	0.51	0.87
Blanket bog, Owennaglogh R., Co. Mayo	0.38	0.50
Bog near Cromaglan Br., Co. Kerry	0.40	0.63
Blanket bog, Owenmore R., Co. Kerry	0.28	0.80
Bogs without *Schoenus*		
Coom Rigg Moss, North Pennines	1.4	0.50
	2.8	0.50
Rusland Moss, Lancs	1.1	0.80
Blanket bog, near Tongue, Sutherland	1.2	0.73
Woodford raised bog, Co. Galway	1.1	0.78
Raised bog, near Ballinasloe, Co. Roscommon	1.03	1.20

I suggest that *S. nigricans* is excluded from other ombrotrophic bogs in the British Isles by the presence of high concentrations of aluminium ions.

The main source of aluminium in ombrotrophic bogs is probably from atmospheric dust particles. The west coast of Ireland, with its higher humidity and prevailing westerly winds, receives less dust than the rest of the British Isles.

I thank Dr. P. J. Newbould for his help. This work was carried out during the tenure of a Department of Scientific and Industrial Research studentship.

Isolation of *Microsporum gypseum* from Cow-dung

Microsporum gypseum, known as a soil saprophyte of worldwide occurrence, has recently been traced in the soil in cucumber greenhouses[1,2].

Contrary to the findings reported by Alsop and Prior[1], in my survey of Dutch greenhouses no keratinous fertilizers had been added to the soil[2]. In a search for the origin of this soil infection various soil improvers introduced into the greenhouses were tested mycologically using the hair-bait method. Of all materials examined only 'pot-soil', commonly marketed in Holland as a soil improver for the cultivation of cucumbers, yielded a growth of *M. gypseum*.

According to the firm selling 'pot-soil', this preparation consisted of seven different components, that is, various kinds of peat-moor and peat-bog, dune-sand and cow-dung rich in straw content. All component parts were mycologically tested, but only from one of these, namely, cow-dung, was *M. gypseum* isolated.

This finding, together with the fact that nowhere outside the greenhouse could *M. gypseum* be isolated from the soil, gave me an indication that this fungus might have been introduced from outside into the greenhouse. Gentles[1,3] has also directed the attention to this possibility.

Later on, independently of this finding, *M. gypseum* could be traced to a heap of cow-dung on a farm where the labourer had contracted suppurative ringworm caused by *M. gypseum*. For several months the patient's chief duty had been the carrying and spreading of cow-dung into the fields. The heap of cow-dung from which the isolations were made had been lying outside the cow-shed for about a month. Wheat straw was the only other substance apart from cow-dung, both being directly derived from the housed cattle.

These two different cases in which *M. gypseum* could be traced to cow-dung indicate that *M. gypseum* infection in cucumber greenhouses is likely to be a 'man-made infection', this fungus being introduced into the greenhouse during efforts to improve the soil. Moreover, this finding might provide a clue to the ultimate habitat of *M. gypseum*, which accounts for its patchy global occurrence.

N(6)-benzyladenine as a Senescence Inhibitor for Selected Horticultural Crops

A STUDY was undertaken on the post-harvest application of N(6)-benzyladenine (manufactured and patented as '*SD* 4901' by the Shell Development Co., Modesto, California) to certain fruits and vegetables in an attempt to delay the onset of senescence. This is a continuation of investigations into the extension of the storage life of fruits, vegetables, and other products with ionizing radiations[1-3], modified atmospheres[4], antibiotics and antifungal chemicals[5-7], and growth regulators[8].

It has been reported[9] that after a crop is harvested, general degradation sets in. This results in the destruction of the soluble ribonucleic acid. Thus, protein synthesis slows down, and the subsequent disintegration into amino-acids provides a medium for the growth of micro-organisms. As the mechanism of protein formation is disturbed, the pigments and other constituents disintegrate and unedible products become evident. The primary step in the degradation of the soluble ribonucleic acid is thought to involve the loss of the end group adenine. A treatment with N(6)-benzyladenine therefore should provide the necessary adenine and restore the soluble ribonucleic acid molecule. Protein synthesis thus would be maintained and the treated produce would stay fresh for a longer time.

Sweet cherries, cauliflower, endive, parsley, snap beans, lettuce (head, leaf, and romaine), radishes with leaves, bunching onions, and cabbage of prime quality were selected for the experiments. Before treatment they were stored at 5 ± 1° C. for a week in an attempt to accelerate enzymatic activity. Such acceleration seemed desirable to convert complex carbohydrates into sugars which would then be available in larger amounts over a longer time for the process of respiration. The produce was then dipped for a minute in 5, 10, and 20 p.p.m. aqueous

Table 1 INCREASE IN STORAGE-LIFE OF HORTICULTURAL CROPS BY THE TREATMENT WITH N(6)-BENZYLADENINE (20 P P M) OVER THE NON-TREATED SAMPLES WHEN STORED AT 5° C AND 95 PER CENT RELATIVE HUMIDITY

Crop	Increase storage-life (days)	Crop	Increase storage-life (days)
Sweet cherries	0	Snap beans	4
Cauliflower	2	Parsley	5
Radishes	2	Lettuce—leaf	3
Celery	3	romaine	5
Endive	3	head	7
Bunching onions	3	Cabbage	8

solutions of N(6)-benzyladenine 'Triton *B* 1956' (a product of Rohm and Haas, Philadelphia, Pennsylvania) at 0 1 per cent was used as a wetting agent The treated samples, along with controls (a dip in distilled water containing the wetting agent), were stored at 5 ± 1° C and at 95 ± 2 per cent relative humidity The produce received two additional applications separated by weekly intervals in the early part of the experiments in an attempt to simulate water treatments given by wholesale dealers and grocers Replicates of some of the crops were also used for studying the effects of the chemical and its concentrations on the respiratory behaviour of the produce A respiratory rate based on evolution of carbon dioxide was measured according to the method of Claypool and Keefer[10]

The respiratory rate varies with the crop In general, it is inversely proportional to the storage life and subsequent marketability of the fresh produce For some of the treated vegetables the respiratory rates (to be published in detail elsewhere) decreased over time This was attributable to the application of the N(6)-benzyladenine which prolonged the storage life and marketable quality by delaying the onset of senescence of the several crops treated (Table 1)

Detailed investigations along the lines discussed are contemplated in co-operation with local wholesale dealers, grocers, and the Shell Development Company Effects of pre-harvest treatments with N(6)-benzyladenine on the post-harvest storage of fruits and vegetables may also be studied

Response of Plants to Root-absorbed Chemical Growth Substances applied in Culture Solutions

A CONTINUOUSLY available supply of biologically active chemicals from a large external pool during the course of experimentation with higher plants is often desirable Foliage sprays or μl solution applications of growth substances to the vegetative tips of plants result in the imposition of heroic dosages to restricted parts Such treatments constitute a crude approach in duplicating an endogenous synthesis and in maintaining physiologically tolerable levels in the plant

Table 1 PHYSIOLOGICALLY EFFECTIVE DOSAGES IN NEGATIVE LOG MOLAR CONCENTRATIONS OF SEVERAL PLANT-GROWTH SUBSTANCES ADDED TO AERATED CULTURE SOLUTIONS USED AS THE ROOT-GROWTH MEDIUM

Plant growth substances*	*Cucumis sativus* L	*Lycopersicon esculentum* Mill	*Pisum sativum* L

Kinetin (3-furfurylaminopurine)	5–6	5–8	5–6
2-Chloroethyl trimethylammonium chloride and related compounds	3–5	4–7	3–5
2,3,5-Triiodobenzoic acid	5–6	4–6	—
Maleic hydrazide	4–5	4–5	—
2,4-Dichlorobenzyltributylphosphonium chloride	4–5	—	—
α-Naphthaleneacetic acid	5–8	—	—

* Gibberellin A_3 supplied by Merck and Co , Rahway, New Jersey, 2-chloroethyl trimethylammonium chloride supplied by Dr N E Tolbert, Michigan State University and the American Cyanamid Co , Stanford, Connecticut, maleic hydrazide by the Naugatuck Chemical Co , Naugatuck, Connecticut, 2,4-dichlorobenzyl tributylphosphonium chloride supplied by the Virginia-Carolino Chemical Corp , Richmond, Virginia

A suggested approach is to add the test chemical to the root medium commonly used in growing plants in aerated culture solutions[1] The method is reproducible and offers control of the duration of exposure to the chemical stimulus Absorption-rates for isotopically labelled compounds may be determined, and changes in root growth as well as in aerial parts observed

Recently, several plant-growth inhibitors have been applied to the soil in which the roots are growing[2-4] Results of the biological activity are often unreliable and difficult to interpret because of many soil-imposed variables cation fixation, micro-organism destruction, leaching, and unequal distribution of the applied chemical For evaluating 'steady state'[5] growth responses of plants it should be advantageous to apply chemical stimuli separately or in combination to the culture solution The solutions can be renewed at will

Addition of plant-growth substances to aerated culture solution also provides a means of recording responses to chemicals such as kinetin, which are often ineffective when applied by other methods[7] Compounds, such as 2-chloroethyl trimethylammonium chloride and 2,4-dichlorobenzyl tributylphosphonium chloride are often toxic as foliar sprays, but give a marked response when added to culture solution

The culture solution technique, however, is not without some of the limitations encountered in other methods of applying biologically active compounds to intact plants Micro-organism destruction may be minimized, but not eliminated Oxidation *p*H inactivation, and chelation by heavy metals may occur Also, the marked sensitivity of roots to some chemicals may result in morphological changes which may produce indirect as well as direct effects on other plant parts

The response-range of higher plants to several plant-growth substances added to aerated culture solution are summarized in Table 1 The negative log molar values are in close agreement with concentrations used in examining growth responses of detached tissues, and for seed germination

Attention has recently been directed to the culture of isolated apical buds in solutions of various chemical stimuli[8,9] The culture solution technique for exposing plants to biologically active substances is, in many respects, comparable and has the advantage of retaining the identity of the intact plant

Isolation of Esculetin from Sweet Potato Roots with Black Rot

UMBELLIFERONE and scopoletin have been isolated from the sweet potato roots injured by the black rot disease due to the infection of *Ceratocystis fimbriata*[1] Formation of esculetin (6,7-dihydroxycoumarin) was also indicated on the basis of paper chromatography, but the actual characterization has remained open This communication presents the evidence for the production of esculetin in the pathogenically degenerated sweet potato root tissue

Coumarin containing fractions extracted from the fungus-degenerated root tissue (48 hr after the black rot infection) by ethanol was transferred to 5 per cent sodium carbonate solution, which was continuously extracted with ethyl ether for about a week after adjusting the *p*H to 6 5–6 8 by dilute sulphuric acid and adding sodium phosphate at the final concentration of 1 *M* (*p*H 6 5) After concentration of the extract, condensed coumarin materials were applied to a column embedded by silica gel, eluted first with chloroform to obtain umbelliferone, scopoletin and other unknown fluorescent substances, and secondly with ethyl acetate Concentrate of the latter eluate was again applied to the silica gel column and was continuously eluted with 30–70 per cent ethyl acetate in *n*-hexane The two main fluorescent substances were found, and the initially moving component was proved to be caffeic acid by the isolation in a crystalline form It did not show the depression of the melting point when mixed with the authentic sample Isolation of caffeic acid from the same source had been reported already by one of us[2] The later moving fluorescent component was devoid of caffeic acid chromatographically, and evaporation of the eluate gave a crude crystal By the vacuum sublimation (3 5 mm , 170°–180°), a light yellowish crystal was obtained and was further recrystallized from dil-methanol Its melting point was 269 5° (decomp corrected) and did not show the depression on mixing with the authentic sample of esculetin Homogeneity of the esculetin fraction at the final purification step was conveniently verified by the silica-gel chromatostrip technique[3] (solvent: water-saturated *n*-butanol) and by paper chromatography (solvent ethanol/conc ammonia/water, 80 · 5 15, or water-saturated *n*-butanol) The detection was carried out by spray of ferric chloride reagent or Haphner's reagent, as well as by exposing to ultra-violet light, under which esculetin gave white greenish-blue fluorescence and was strongly intensified by ammonia gas Ultra-violet spectra of the isolated esculetin were identical with those of the authentic esculetin λ_{max} (ethanol) 230 mμ (log ε 1 35 (sample), 1 34 (ref), 258 mμ (log ε 3 23 (sample), 3 77 (ref), 300 mμ (log ε 3 62 (sample)), 3 58 (ref), 351 mμ (log ε 10 3 (sample)), 9 9 (ref) They were in conformity with the data of Goodwin and Pollock[4] Infra-red spectra of isolated esculetin was also perfectly in agreement with those of the authentic substance

Whereas the production of coumarin compounds in the diseased plant tissue is a rather common event[5–8], so far as we are aware, it is the first finding on the synthesis of this specific coumarin derivative The magnitude of the esculetin synthesis in the fungus-infected root tissue was found to be far below that of umbelliferone and scopoletin, but the present observation would be of value for the further investigation on the biosynthetic mechanism of coumarins in general as well as for the metabolic change of the diseased plants associated with the physiological role of esculetin in the fungus infection

Production of Monocaryons in Basidiomycete Cultures by the Action of Toxic Chemicals

MOST basidiomycete cultures, whether isolated from decay in wood, from portions of basidiocarps, or from spore casts, are dicaryotic Monocaryotic mycelia needed for special investigations, such as interfertility testing, are usually obtained from single basidiospores Monocaryons may, however, arise directly from the dicaryotic mycelium of some species during culture on artificial media, and in most species they can be produced from dicaryons by microsurgery[1,2], by high-speed blending[3,4], or by the action of cholic acid derivatives[5]

During extensive laboratory use of *Lenzites trabea* (Pers) Fr as a test fungus, we observed several instances of reversion to the monocaryotic condition, both on normal malt agar media and, more frequently, on media containing high concentrations of arsenate. Since these changes affected our tests, a detailed study of the causes of reversion was made *Lenzites trabea* is very suitable for this work as the dicaryons have abundant clamp connexions and a yellowish silky culture, while the monocaryons have abundant oidia and often a distinctive white powdery culture

In these investigations, all strains of *L trabea* studied tended to revert to the monocaryotic condition when grown on nutrient agar containing sodium arsenate in concentrations sufficient strongly to

Table 1 Toxic Agents responsible for Monocaryon Production

Species	Isolate	Toxic agent	Concentration* (M)

Poria pirongia G H Cunn	*DFP*4036	$CuSO_4$	0 005
Poria hyposclera (Berk) Cke	*DFP*6406	$CuSO_4$	0 025

* Lowest concentration of toxic agent in nutrient medium (glucose, 2 0 per cent, peptone, 0 4 per cent, KH_2PO_4, 0 6 per cent, $MgSO_4$-$7H_2O$, 0 3 per cent, thiamine, 0 003 per cent, agar, 1 5 per cent) at which monocaryons were produced

retard, but not to inhibit growth Moreover, we have found that the change can be induced by copper sulphate or by zinc sulphate as well as by arsenate, and that it occurs with other basidiomycetes Examples are given in Table 1

These results suggest that reversion to the monocaryotic condition may be a widespread response of basidiomycete cultures to growth-retarding chemicals, although all species are not changed by the same conditions Some species did not produce monocaryons at all under our test treatments, and further tests of other concentrations and of other toxic agents are being conducted with these

The monocaryons produced can be mated with other monocaryons, produced either in the same way or by monospore culture, to give normal dicaryotic mycelium This enables interfertility testing of cultures for conspecificity to be done without the usual necessity for the production and isolation of basidiospores, a task which is always time-consuming and which, for many species, is very difficult or impossible We have already used this technique in the interfertility testing of a number of basidiomycete cultures and think that, with further improvements, it will prove a valuable procedure in the experimental taxonomy of basidiomycetes

The mechanism of monocaryon production is still obscure By cross-mating the monocaryons produced by *L trabea* (a bipolar heterothallic species) and using the mating factor genes as markers, we have found that all monocaryons produced from the one dicaryon by the one toxic agent tend to carry the same nucleus of the original pair, suggesting that monocaryon production involves a very high degree of nuclear selection This could be of importance in genetic studies of basidiomycetes

The ready production of monocaryons by the addition of toxic agents to the nutrient agar substrate suggested that they might also occur in the treated wood blocks used in standard laboratory evaluation tests of preservatives against wood-destroying basidiomycetes Proof of this was harder to obtain since both microscopic examination of mycelium in the block and culturing of monocaryons from the block presented difficulties, but we have demonstrated the production of monocaryons by *L trabea* in test blocks treated with copper chromate (0 1 lb /ft ^{3}), or with copper chrome arsenate (0 2–1 0 lb /ft ^{3})

These findings suggest that many of the published measurements of 'total inhibition point' (for agar toxicity studies) or of 'threshold value' (for 'soil block' or 'agar block' decay tests) refer, not to the dicaryotic cultures used as inoculum, but to derived monocaryons which could differ appreciably in growth-rate, wood-destroying ability and tolerance of preservatives Though we do not consider that this would, in practice, have any great effect on the evaluation or comparison of preservatives, it may influence some investigations, especially where the test fungus is re-isolated from a treated substrate for future use

Investigations on the range of conditions responsible for monocaryotization, on the role of nuclear selection and other postulated mechanisms, and on the proportion of wood-destroying fungi affected are proceeding and will be reported in detail elsewhere

RADIOBIOLOGY

Prolonged Survival of Skin Homografts in Adult Mice following Sub-lethal Irradiation, Injection of Donor-Strain Spleen Cells and Administration of A-Methopterin

It has been reported previously from this laboratory[1] that a high proportion of adult *A*-strain mice exposed to 500 r whole-body irradiation followed by the injection (divided between the intraperitoneal and intravenous routes) of 800 million–1,200 million $(CBA \times A)F_1$ hybrid spleen cells, become specifically tolerant of homografts of $(CBA \times A)F_1$ skin On the other hand, four of five *A*-strain mice which received 500 r whole-body irradiation and 700–800 million *CBA* spleen cells died after intervals ranging from 6 to 25 days with clinical and pathological signs of graft-versus-host disease, and the solitary survivor showed no tolerance to *CBA* skin

The observation of Russell[2] that the development of fatal graft-versus-host disease in new-born *C57BL* mice which received 5–15 million spleen cells from adult *DBA*/1 donors could be prevented by administration of *A*-methopterin, and that many of the surviving animals did not reject subsequent homografts of *DBA*/1 skin, suggested that it would be of interest to study the effect of *A*-methopterin in sub-lethally irradiated adult mice which received a potentially fatal dose of allogeneic spleen cells

Sixteen *A*-strain male mice were given 500 r whole-body irradiation by the technique previously described, followed by the intravenous injection of 150 million nucleated spleen cells from male *CBA* mice twice daily for two days, starting on the day of the irradiation (that is, a total of 600 million nucleated cells) Four mice received no further treatment, the remainder were given *A*-methopterin in a dosage of 1 5 μgm /gm body-weight every 2 days for six doses, starting 2, 6 or 10 days after the irradiation Four weeks after irradiation all surviving mice received a homograft of skin from a *CBA* male donor

The length of survival of the recipients and the behaviour of the skin grafts is shown in Table 1

It will be seen that the incidence of fatal graft-versus-host disease was greatly reduced by admin-

Table 1

Time of starting *A*-methopterin	Survival of animal from day of irradiation (days)	Appearance of skin grafts 6 weeks after transplantation
Not given	9, 12, 19, 27	
10 days after irradiation	9*, 10*, 12, 13	
6 days after irradiation	7, 14, 28†, >70	Graft on surviving animal shows good hair growth, and no contraction or scabbing
2 days after irradiation	56, >70, >70, >70	Two animals have grafts showing no contraction or scabbing, but with only sparse hair growth The other two rejected their grafts in less than 10 days

* These animals actually died before the first dose of the drug had been given

† Accidentally killed at time of grafting

>70 implies animal alive and well 70 days after irradiation

istration of *A*-methopterin starting on day 2 (reckoning the day on which the irradiation and first spleen cell injection was given as day 0), and reduced to a lesser extent by administration of the drug starting on day 6 Moreover, 3 of the 5 surviving animals have so far shown no evidence of reaction against skin homografts from mice of the strain which provided the spleen cells

It seems likely that the animals with long-surviving skin grafts are lymphoid chimæras and that the non-reactivity to the skin grafts is a manifestation of specific immunological tolerance This is being investigated (*a*) by experiments with donors carrying the *T*6 chromosomal marker, (*b*) by using the Simonsen discriminant assay as described in the earlier study[1] The results will be reported fully elsewhere.

I thank Mr J R Wilson, of Lederle Laboratories, for a supply of *A*-methopterin ('Methotrexate')

ENTOMOLOGY

Environmental Influences in Sex Determination in the Hymenoptera

MOST Hymenoptera reproduce by arrenotoky (unfertilized eggs giving rise to males and fertilized eggs to females), but some species reproduce by thelytoky (unfertilized eggs producing females, males being generally absent), and other species by deuterotoky (unfertilized eggs producing both males and females) With rare exceptions, males are haploid and females diploid irrespective of the mode of reproduction, though haploidy and diploidy are not necessarily sex determining in themselves, as it is known in a few species that sex determination depends on multiple sex alleles

The demarcation between thelytoky and deuterotoky is obscured by the occasional production of males in many thelytokous species In the uniparental *Ooencyrtus submetallicus*, which is usually thelytokous, males and sex intergrades (regarded as gynandromorphs) are also produced, and it has been shown that sex is determined by the temperatures to which the female is exposed during development and oviposition[1,2] In this species, environmental temperature determines whether reproduction is by thelytoky or arrenotoky (though females are not produced arrenotokously as the males are not reproductively functional), and deuterotoky consists of the occurrence of arrenotoky and thelytoky in the same female, and is not a distinct mode of reproduction

In a culture of *Ooencyrtus submetallicus*, there appeared an aberrant strain that produced male, female and gynandromorphic progeny at temperatures at which the normal strain produced almost entirely female progeny (A paper dealing with this matter will be published soon) In the normal strain the cytological processes on which sex determination depends are evidently temperature-sensitive, so that parentally experienced temperatures determine whether an egg develops into a male, female, or gynandromorph It appears that in the aberrant strain this temperature-sensitive mechanism has been disrupted by genetic change, so that male, female, and gynandromorphic progeny are all produced in an uncontrolled manner, irrespective of environmental temperature The evidence in uniparental Hymenoptera for association of thelytoky with low temperature and of arrenotoky with high temperature[3] is sufficient to suggest that temperature-sensitive mechanisms controlling sex determination may not be uncommon in uniparental species

Thelytoky sometimes occurs in arrenotokous species (as in the production of queens and workers from unfertilized eggs in the honey-bee[4]), and it is possible that many, if not all, hymenopterous species can produce both sexes uniparentally[3] It is therefore possible that the cytological processes underlying sex determination may be subject to environmental influence in arrenotokous species as well as in thelytokous species, and that many or all hymenopterous species are potentially both arrenotokous and thelytokous, but appear to be only one or the other because of their specific cytological reactions to the temperatures or other environmental factors to which they are usually exposed

A related matter is the occurrence of sex intergrades It is reported in *Habrobracon juglandis* that more male mosaics and gynandromorphs are produced at high temperatures, and in the honey-bee that eggs exposed to low temperatures produce more gynandromorphs, and that a lowering of hive temperature is thought to result in more mosaics for sex[5] In the normal strain of *Ooencyrtus submetallicus* gynandromorphs are produced under particular temperature conditions These facts indicate that environmental temperatures may be important in the production of sex intergrades in both arrenotokous and thelytokous species Also, strains of honey-bee are known that have a hereditary tendency to produce large numbers of gynandromorphs[6] These strains are reminiscent of the aberrant strain of *Ooencyrtus submetallicus*, which regularly produces gynandromorphs irrespective of temperature This suggests that in arrenotokous species with an hereditary tendency to produce gynandromorphs genetic change may have disrupted some mechanism controlling sex determination, as appears to have occurred in the aberrant strain of *Ooencyrtus submetallicus*

Sex determination and the production of sex intergrades in the Hymenoptera undoubtedly have a cytological basis, and it is appropriate that most research on them should be cytological in character. However, it is becoming very clear that proper understanding of the cytological and hereditary aspects of these problems cannot be achieved without paying adequate attention to the influence of environmental factors on the processes concerned

Absence of Natural Volatile Solvents in Cockroach Grease

THE wax layer generally present in the epicuticle of insects is important because it reduces loss of water by evaporation[1-3] Except possibly for the cricket[4], there has not been sufficient knowledge of the chemical composition of the cuticular wax of any insect to formulate with certainty a physico-chemical basis for the physiological action of the wax[5] A detailed chemical analysis will be published (with Miss M E Cox) of the soft grease extracted from the cast skins of cockroaches Since the preparation of the grease involves recovery from organic solvents, any natural volatile solvents still present in cast skins would not be detected by our techniques Accordingly, attempts reported here were made to distil volatile compounds from the surface of freshly killed cockroaches

Tests for the presence of volatile substances were made directly on specimens of *Periplaneta americana* (L) The glass apparatus was similar to that described[6] for the transfer of gas chromatographic fractions boiling over 60° A specimen container and a capillary for collection of samples were connected by a tube which could contain solid desiccants Since desiccants such as magnesium perchlorate and calcium sulphate also trap alcohols, duplicate runs without desiccant were made and, if an aqueous distillate was obtained, this was extracted with hexane In use, the specimen container was held for at least 1 hr in liquid air before the whole apparatus was evacuated to a pressure of less than 0 01 torr The source of vacuum was removed and the liquid air bath transferred to the capillary collector Distillation under vacuum was allowed to proceed for 2–3 hr after the specimen container had reached room temperature Any distillate or its hexane extract was examined by gas chromatography at a number of temperatures to 200° with a 4-ft column of 5 per cent 'Apiezon *L*' on 'Celite' and by infra-red spectroscopy

When cockroaches, usually 4 in each experiment, were subjected to distillation without desiccant, water and other unidentified volatile constituents were collected If the mouthparts and anal regions of the insects were sealed with paraffin wax, no volatile materials other than water were condensed Even warming of the insects with an infra-red lamp failed to drive off volatile organic compounds Negative results were obtained also with freshly moulted cockroaches tested while still white

The absence of volatile solvents in the surface grease of the cockroach has possible implications in the mechanism of wax secretion[7] and was unexpected since Beament[5] has suggested that volatile paraffins and alcohols of chain-length C_8–C_{12} are present in the soft grease Such solvents provide a plausible explanation of changes observed such as the hardening with time of extracted grease In the present experiments, when 5-µl samples of solvents such as the primary *n*-alcohols, butanol, octanol and decanol, octan-2-ol, and the *n*-hydrocarbons, hexane, octane, decane, dodecane, tridecane and hexadecane were spread on the cuticles of cockroaches, quantitative recoveries and identifications were made Further evidence that particular solvents are absent is the observation that 1 µl of octanol run on to cockroach cuticles caused an immediate loss by the insects of the power of co-ordinated movement followed by death in a few hours Similarly, amounts of 20 µl of dodecane killed one-third of cockroaches tested, while 40 µl killed two-thirds of test samples With the collection techniques used, it was possible to detect volatile solvents, if present, in amounts less than 0 1 per cent by weight of the 0 5 mgm of cuticular grease present per cockroach

The current chemical analysis mentioned earlier has already shown that, besides saturated hydrocarbons and fatty acids, the grease from cockroach cast skins contains unsaturated hydrocarbons in large amount, unsaturated fatty acids and a number of aldehydes The presence of these more reactive types of compound suggests the possibility that changes in the properties of cockroach grease during ageing[5] may have a chemical basis

Steroid Hormone in an Insect, *Bombyx mori*

IT is well known that the metamorphosis of insects is brought about by two hormones, one secreted by the brain and the other by the prothoracic gland The brain hormone activates the prothoracic gland and directly induces metamorphosis with ecdysone[1]

The extraction of the hormone from brains of insects was first reported by Kobayashi and Kirimura[2] Until recently, only a few workers[3,4] had carried out extraction of active principle from brain or central nerve system in insects At present we have succeeded in crystallization of the brain hormone in the silkworm, *Bombyx mori*[5]

This communication deals with the further progress conducted on the chemical character of the brain hormone and with the results obtained on bioassay of the hormone and of its related compounds

The melting point of the crystal (142°–143° C) which was reported previously[5] remained unchanged by recrystallization and no ultra-violet spectrum of the crystal was found The infra-red spectrum of the crystal in potassium bromide showed that it has a $RR'C = CR''H$ type band which was characteristic in the region 750–850 cm^{-1}, and a hydroxyl band which was shown at 3,480 cm^{-1} Furthermore, the characteristic absorption spectrum of crystal was very similar to that of pure cholesterol in all regions The crystal was also analysed by means of gas chromatography with a Barber Colemann model 10 with argon ionization detector. This result showed that there was one main peak with trace amounts of three peaks and that the retention time of the main peak coincided favourably with that of pure cholesterol. Therefore, we are inclined to believe that the crystal was cholesterol accompanied with trace amounts of three impurities.

15 mg of crude sterol mixture was collected from several active fractions of brain hormone extract by the counter-current distribution method and then acetylated in pyridine by a common method. The elute was collected carefully after the acetylated sterol mixture was adsorbed to 5 g of aluminium oxide (according to Brockmann) column and eluted with *n*-hexane. White needle-like crystals of acetylated sterol were formed on recrystallization with acetone and methanol after the solvent was evaporated from the elute. Following further purification by recrystallization the melting point of the crystal became constant at 115°–116° C.

After the purified acetylated sterol was saponified with alcoholic potash solution, 2 mg of crystal was obtained by recrystallization with acetone and methanol. The crystal appeared as pearly leaflets or plated forms when crystallized with dilute alcohol. The melting point of the crystal was 148° C, and also the mixed melting point of the crystal and pure cholesterol mixture was determined to be the same as that of the crystal alone.

The chemical character of purified brain hormone is summarized as follows: no ultra-violet spectrum was found; the infra-red spectrum was identified with that of pure cholesterol; the Liebermann–Burchard reaction was positive; a gas chromatogram exhibited only one peak; m.p. was 148° C.

From the above-mentioned results, it was determined that purified brain hormone was identical with pure cholesterol.

Table 1. BRAIN HORMONE ACTIVITY OF ISOLATED PURE CHOLESTEROL

Dose of cholesterol (μg)	No. of 'Dauer-pupæ' used for bioassay	No. of moths emerged*	Days from injection to emergence	No. of dead individuals
10	6	4	15–23	0
2	6	5	18–23	0
0.2	6	4	17–23	1
0.02	6	3	18–27	3
0	24	0	—	0

* The results obtained for 30 days at 25° C following injection.

The results of bioassay are as follows. The diapausing pupæ of *Bombyx mori* following extirpation of the brain ('Dauer-pupæ') were used as test objects for the assay of brain hormone activity. They were then observed for about 6 weeks at 25° C prior to use. 0.01 ml. of sterol dissolved in 9 per cent ethanol was injected into each test animal. In the first experiment, when the aforementioned isolated pure cholesterol was injected into the 'Dauer-pupæ', the test animals emerged as moths. Positive results of the brain hormone activity were obtained for dosages up to 0.02 μg in pure cholesterol injections as shown in Table 1.

In the second experiment, two kinds of sterols related to cholesterol, cholestanol and 7-dehydrocholesterol were used as dosages for bioassay of brain hormone activity. When each of the sterols, 2 μg of cholestanol or 10 μg of 7-dehydrocholesterol, was injected into three 'Dauer-pupæ' respectively, the following results were observed. In the case of cholestanol, two out of three 'Dauer-pupæ' injected became moths in 16–19 days following injection but the other animal remained in the pupal form without any differentiation for 30 days following injection. In the case of 7-dehydrocholesterol, two out of three 'Dauer-pupæ' became moths in 19 days, while the other animal remained in the pupal form for 30 days. From the aforementioned experiment it seems that these two chemicals also have brain hormone activity, but to a lesser degree than cholesterol.

In the third experiment, 100 μg of each of the following chemicals, β-sitosterol, stigmasterol and ergosterol, respectively, was injected into three groups of six 'Dauer-pupæ'. Two of six animals tested with each chemical, in every group, emerged as moths from 14 to 29 days following injection. A total of six individuals in this experiment died, but no other animals emerged for 30 days. However, no moth was obtained in 30 days for twenty control animals following non-injection and/or mock injection by 0.01 ml. of 9 per cent ethanol alone. From these results, it appears that these three chemicals do display brain hormone activity, even though the results of this bioassay were inconclusive. It is concluded that cholesterol is an active principle of the brain hormone, and its related compounds, such as cholestanol and 7-dehydrocholesterol, also have a certain degree of hormone activity.

Generally speaking, cholesterol is the main sterol of most insects and also phytosterols derived from diet are found in phytophagous insects. Most insects, however, cannot synthesize cholesterol from substances which are known to be cholesterol precursors in both mammals and micro-organisms. Although information on the hormone activity of sterols in insects was previously not forthcoming, it has been shown here that sterol is an active hormone in insects.

Considering the importance of sterols and cholesterol precursors as insect hormone, we are currently investigating hormone activity of these compounds in insects.

We thank Prof. G. Tamura, Prof. S. Hara, Dr. T. Iwashige, Dr. G. Chihara, Dr. S. Okabe, and Dr. H. Endo for their invaluable assistance.

MICROBIOLOGY

Identification of a New Type of Colicine (Colicine L)

THE strain *Escherichia coli* 398 of the collection in this Institute produces a colicine, which cannot be identified as one of the known types[1–3]. This new type is related to the colicines of the group *E*, and was at first considered to be a complex colicine, containing colicines *E* and *I*. A more detailed analysis of some biological characteristics, however, showed that this colicine can be considered as a new type. The letter *L* was given as an index to this new type, since the other colicines were identified in a similar manner[2]. In this communication are summarized experiments showing how colicine *L* can be distinguished from the other types.

(1) *Activity.* As other colicines, colicine *L* is active against strains of Enterobacteriaceae, particularly against some strains of *Escherichia coli*, but inactive against *Micrococcus*, *Pseudomonas* and *Mycobacterium* (Table 1). Tests of sensitivity were made by the method of perpendicular streaks[4].

Tests of several hundred wild strains of *E. coli* isolated from human or animal fæces showed that the activity of colicine *L* is quite different from that of 14 other colicines (colicines $V, B, E, I, K, S_3 + I, D, S_4, F, J + I, A, C, H$ and X). These results suggest that colicine *L* cannot be considered identical with any of the others. Nearly 20 per cent of *E. coli* isolated from human fæces are sensitive to colicine *L*, while the percentage of the same strains sensitive to the other 14 colicines varies from 0 to 60 per cent. This is in favour of testing sensitivity of enteropathogenic *E. coli* for epidemiological purposes, as serotypes and phage types of these micro-organisms can be subdivided into several colicinotypes[5].

(2) *Specificity of resistant 'mutants'.* Mutants resistant to colicine *L* obtained from the strain *E. coli* Row[6] are not always specific, as, for example, mutants resistant to colicine *X*[3]. This is the reason it has been difficult at the beginning to identify this type of colicine as a new type. Colicine *L* was not found to be related to colicines V, K, D, A and X, because no cross-resistances to these five colicines were observed. However, cross-resistances were found between colicine *L* and colicines $B, E, I, S_3 + I, S_4, F, J + I$ and C. It is interesting that 5 out of these 8 colicines ($E, F, J + I, S_3 + I$ and S_4) belong to the group of colicine *E*. Cross-resistances of mutants derived from several strains of *E. coli* concerning colicines which are not identical have been already reported by Fredericq[2] and one of us[7].

It was therefore necessary to extend this part of the work in several mutants resistant to different colicines. In experiments done with 20 mutants of four different lines of the strain *E. coli K*12 resistant to colicine *L* we found that cross-resistance between colicine *L* and colicines $B, E, I, S_3 + I$ and $J + I$ do not exist. It was therefore concluded that colicine *L* is not identical with any of these 5 colicines.

Further experiments were designed for the examination of cross-resistances between colicine *L* and colicines S_4, F and C, showing still cross-resistances when lines of *E. coli K* 12 were used. The examination of the other 20 mutants derived from *E. coli* Row, resistant to one of the colicines S_4, F and C, showed that these mutants are not resistant to colicine *L* and proved that also these colicines are not identical with colicine *L*.

This series of experiments shows that colicine *L* is probably related to the group *E* of colicines; however, it is not identical with any of the colicines of this group.

(3) *Morphology of the inhibition zones in agar.* For the examination of the morphology of inhibition zones, the colicinogenic strain is stabbed in nutrient agar and incubated at 37° for 48 hr. The stab cultures are sterilized by chloroform vapour and the indicator strain is seeded over the surface of the agar plate by the double-layer method[4,6]. As for other colicines, the zones of inhibition are different when different sensitive indicator strains are used. For the strain *E. coli* Row the diameter of the zone of inhibition in Difco nutrient agar plates is about 22 mm. Colonies resistant to colicine *L* are rarely found within the zone of inhibition, when *E. coli* Row is used as indicator. However, several small colonies, which are not resistant to colicine *L*, are seen near the edges of the zone of inhibition. The edges of zones of inhibition are well defined.

Table 1. SPECTRUM OF ACTIVITY OF COLICINE *L*

Genus or species	No. of strains examined	No. of strains sensitive
Enterobacteriaceae		
Escherichia coli	100	22
Citrobacter	15	1
Klebsiella	25	0
Salmonella	25	0
Proteus	25	0
Serratia	13	0
Other micro-organisms		
Micrococcus	40	0
Pseudomonas	30	0
*Mycobacterium**	25	0

* Strains able to grow in ordinary media within 48 hr.

When lines of *E. coli K* 12 are used as indicators the zones of inhibition are also about 22 mm., but a greater number of colonies resistant to colicine *L* are observed within the zone of inhibition.

(4) *Diffusibility in agar.* Colicine *L* diffuses relatively slowly in Difco nutrient agar plates. It diffuses more slowly than colicine *V*, but more rapidly than colicines *E* and *I*. In one experiment performed with *E. coli* Row as sensitive indicator, the zone of inhibition measured daily for five consecutive days was as follows: 1 day, 13 mm.; 2nd day, 22 mm.; 3rd day, 26 mm.; 4th day, 30 mm.; 5th day, 34 mm.

(5) *Heat resistance.* Heat resistance tests were made in a suspension of a culture of the strain *E. coli* 398 sterilized with streptomycin and containing 128 arbitrary units of colicine *L* per ml. of suspension. The medium used for the culture of *E. coli* 398 contained 30 gm. of Difco casamino-acids and 10 gm. of Difco yeast extract per 1,000 ml. of water. The method of titration in arbitrary units will be published elsewhere.

Results of heat resistance appear in Table 2. Colicine *L* is rapidly destroyed at 100° C., but resists a temperature of 72° C. for 30 min., though the titre falls considerably.

(6) *Sensitivity to proteolytic enzymes.* A suspension of colicine *L*, produced as already described and containing 32 arbitrary units per ml., became inactive after 15 min. action of trypsin at 37° C. In the same suspension, it resisted papaine for 24 hr. at 37° C., but the titre fell from 32 to 4 arbitrary units at the end of the experiment.

Bacterial proteases do not destroy (at least completely) colicine *L*, which resisted the proteases of 4 strains of *Proteus* and of 4 strains of *Pseudomonas*. The method used for the action of bacterial proteases has been described by Gratia and Betz-Bareau[8] and by Fredericq[2,4].

(7) *Filtration.* Colicine *L* is not able to pass through Chamberland *L*5, Seitz *EK* and Hemmings[9] filters.

(8) *Production in different media.* The concentration of colicine *L*, measured in arbitrary units, is variable in different culture media. A good titre was obtained in the following media: Difco nutrient broth additioned with 10 per cent bovine serum,

Table 2. HEAT RESISTANCE OF COLICINE *L* (IN A MEDIUM CONTAINING 128 ARBITRARY UNITS PER ML.)

Time (min.)	Arbitrary units per ml. after heating at 100° C.	Time (min.)	Arbitrary units per ml. after heating at 72° C.
2	4	5	32
3	2	10	8
4	2	20	4
5	0	30	4
10	0		

Difco tryptose, Difco tryptone, Difco Todd and Hewitt broth, Difco casamino-acids 3 per cent additioned with 10 per cent bovine serum or 1 per cent yeast extract, undiluted bovine serum.

(9) *Lyophilization and conservation in suspensions.* Lyophilization of colicine suspensions, prepared as described here, does not diminish the titre of colicine. The titre is also well maintained in suspensions at 22° C. or 4° C. for two months. It is possible that colicine *L* keeps well in suspensions for a longer time at 22° C. or at 4° C., without being lyophilized.

Adaptation of *Escherichia coli* to Selenate

SELENIUM compounds are usually considered harmful, but evidence is mounting that the element may have other biological effects. The fact that a few higher plants can accumulate relatively large amounts of selenium has been known since the 1930's, several species of *Astragalus* (vetch) have actually been proved to require traces of selenium for normal development[1]. More recently, animals deficient in vitamin E as well as grazing animals suffering from white muscle disease were found to improve after treatment with selenium in quantities 0·1–0·01 less than the usual toxic amounts[2,3]. It has been suggested that selenium at these concentrations may well be an essential element for animals[3].

Micro-organisms respond to selenium compounds in a variety of ways. Inhibition of growth by selenium and antagonism to selenium by sulphur compounds are well documented and have been reviewed elsewhere[1,4]. Complete replacement of required sulphur nutrients has also been demonstrated, selenopantethine for pantethine[5] and selenomethionine for methionine[6]. An organism capable of oxidizing elemental selenium to selenic acid, much as *Thiobacillus thiooxidans* oxidizes sulphur to sulphate, was isolated in 1923[7]; but whether this organism interchanged selenium for sulphur or whether it needed selenium was not determined.

Several micro-organisms show a tolerance to high concentrations of selenite[8–10], a characteristic that has been used as a basis for the isolation and separation of *Salmonella* species from *Escherichia coli*[8]. An adaptation to a selenium compound is seen from work with *Chlorella vulgaris*, all or most of the cells of which can adapt to withstand the toxicity of selenomethionine[11–12]. Adaptation of a micro-organism to inorganic selenate, however, has not been reported. We describe here experimental conditions under which *Escherichia coli* was found to adapt and grow in the presence of otherwise toxic levels of potassium selenate.

Escherichia coli K_{12} was maintained on nutrient agar slants (Difco). For inoculation, cells were first grown overnight in a liquid medium based on that of Anderson[13]. Because sulphate and selenate act as competitive antagonists, the medium was modified by replacement of magnesium sulphate with magnesium chloride and potassium sulphate to allow control of the sulphate concentration. The composition of the medium was NH_4Cl, 0·0187 *M*, $Na_2HPO_4 \cdot 7H_2O$, 0·0422 *M*; KH_2PO_4, 0·0220 *M*, $MgCl_2 \cdot 6H_2O$, 0·0017 *M*, K_2SO_4, 0·00031 *M*, glucose, 0·0220 *M*. Ammonium and phosphate salts were prepared as one stock solution. Aliquots of the stock solutions were pipetted into 'Pyrex' tubes, 15 mm × 125 mm, matched to fit the Klett–Summerson colorimeter, and enough distilled water was added to give a final volume of 5·0 ml. Potassium selenate was added before sterilization. It was prepared according to the method described by Trelease and Beath[1] in order to ensure the absence of selenite and circumvent the formation of elemental selenium during growth

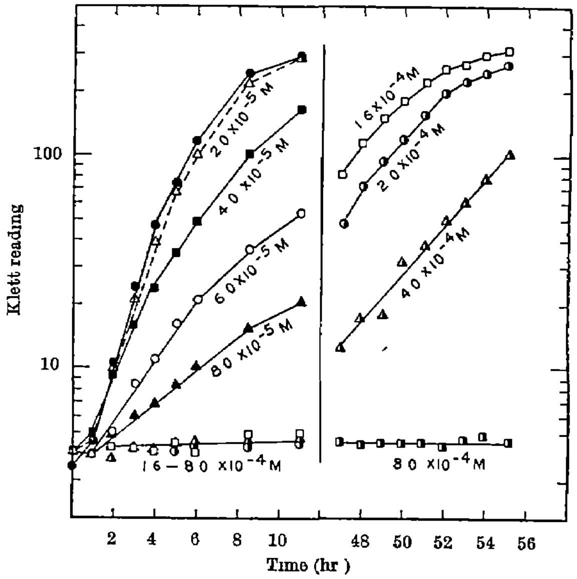

Fig. 1. Influence of potassium selenate on growth of *Escherichia coli* K_{12} in the presence of 2·0 × 10^{-4} *M* potassium sulphate. Numbers refer to molarities of potassium selenate.

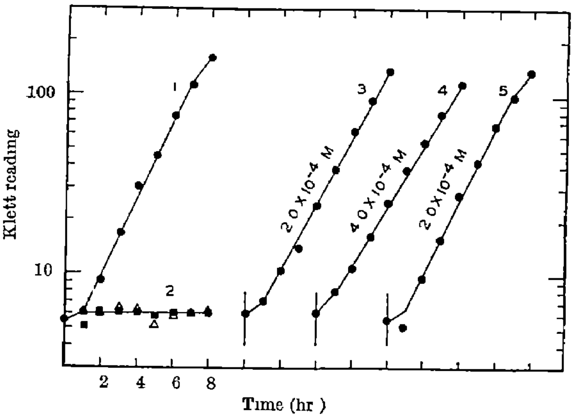

Fig. 2. Growth of selenate-adapted *Escherichia coli* K_{12} with potassium selenate. (1) Unadapted control, no selenate, (2) unadapted control, ■ 2·0 × 10^{-4} *M* potassium selenate, △ 4·0 × 10^{-4} *M* potassium selenate, (3 and 4) adapted cells grown with same level of potassium selenate in which they initially grew, (5) adapted cells previously subcultured on nutrient agar slants free of added selenium. All cultures contained 2·0 × 10^{-4} *M* potassium sulphate. Time scales moved to right for curves 3, 4 and 5.

Glucose and magnesium chloride were autoclaved separately and added after sterilization Autoclaving was at 15 lb for 20 min

Inoculum cells were taken from 14–16-hr old cultures, centrifuged and washed three times with sterile, sulphurless, glucose-free medium The washed cells were diluted until a reading as close to 200 on the Klett as practicable was obtained A 0 1-ml aliquot, when added to the 5 ml of complete medium, gave an initial Klett reading of about 5 Exponential growth began after a short lag of approximately 1 hr To check the adequacy of washing, sulphurless controls were included in each experiment All tubes were prepared in duplicate and were incubated at 37° on a roller tube wheel turning at 5 r p m Readings were made at hourly intervals during the exponential phase of growth and less frequently thereafter in order to observe the effect of the inhibitor on the entire growth curve Filter No 42 (blue) was used to take the Klett readings

With selenate toxicity a function of the sulphate-level[1,4], it was necessary to determine the lowest sulphate concentration that would give an optimum growth response Up to approximately $8\ 0 \times 10^{-5}\ M$, the amount of growth after 24 hr was proportional to the sulphate concentration At higher levels, through $8\ 0 \times 10^{-2}\ M$, there were no differences in the growth curves A sulphate-level of $2\ 0 \times 10^{-4}\ M$ was selected for the experiments described here

The inhibitory effect of serially increased concentrations of potassium selenate is illustrated in Fig 1 A progressive decrease in the exponential growth-rate began at $4\ 0 \times 10^{-5}\ M$, but the final amount of growth equalled that of the uninhibited control At several of the higher selenate-levels, where inhibition seemed to be complete, growth consistently resumed after a lag of 24–48 hr and eventually attained the same maximum as the control Complete inhibition always occurred at a concentration of $8\ 0 \times 10^{-4}\ M$ selenate The effects on growth-rates are similar to those observed in earlier experiments with *Chlorella vulgaris*[14] Adaptation of the alga to selenate, however, was not detected at that time, possibly because maximally inhibited cultures had not been incubated long enough With several other micro-organisms, including *Saccharomyces cerevisiae*[15,16], *Desulphovibrio desulphuricans*[17], and *Aspergillus niger*[18], inhibition of growth is also a function of selenate concentration In those experiments, however, growth was measured at an arbitrarily chosen time interval Rates of growth and lag periods were not measured, therefore, any adaptation would have been overlooked

To determine whether cultures that had resumed growth were now resistant to selenate, cells were prepared for inoculation as described here and inoculated into fresh medium identical with that from which they had been withdrawn Controls with unadapted cells were run simultaneously Fig 2 (curves 3 and 4) shows that the prolonged lag typical of adapting cultures was eliminated The cells were now able to grow exponentially at a rate almost equal to that of the unadapted control and reached the same maximum densities Growth of adapted cells in sulphate alone was no different from that of the control

Adapted cells, when re-exposed to selenate after nine transfers on nutrient agar slants free from added selenium over a twelve-day period, nevertheless remained adapted (Fig 2, curve 5) The adaptation under these conditions therefore appears to be a stable one

The work was supported by a grant, *RG*-9086, from the U S National Institutes of Health

CYTOLOGY

Ring Chromosomes in Human Beings

RING chromosomes have been found in some species, the most intensively studied being maize[1] and *Drosophila*[2] They have also been induced by irradiating human cells *in vitro*[3] and are known to occur in human tumours[4] We have recently found a ring chromosome in two children, a different chromosome being involved in each case There are no apparent signs of neoplastic disease in either patient

In Winnipeg, Manitoba, the chromosomes of a male infant with multiple congenital anomalies have been studied by the blood culture technique[5] The child resembles somewhat the 18 trisomy syndrome[6], with rather odd-looking facies, large abnormal ears, small mandible, epicanthic folds, right inguinal and umbilical hernias, limited hip abduction, high arched palate and a simian crease on the right palm He has had several minor motor seizures, is failing to thrive and at 5 months of age gives little evidence of intellectual progress The mother, age twenty-four years, has a history of pelvic X-ray exposures prior to conception She had X-ray pelvimetry during a previous pregnancy complicated by an iniencephalic fœtus She later had diagnostic X-rays for fractured lumbar vertebræ

In all of more than 100 cells examined one of the large acrocentric chromosomes in group 13–15 is missing, being replaced by a ring-shaped chromosome The size of the ring appears to be constant with the exception of a few large ones (Fig 1) The total number of chromosomes in every cell analysed is 46 One member of chromosome 3 has a submedian centromere and is larger than its homologue Since this infant has many of the anomalies found in 18 trisomics we suspect that a translocation of a piece of the 18th chromosome is present

In London, Ontario, chromosome studies were carried out on a patient during investigation of mental retardation The mother was twenty-three years old at the time of the patient's birth, having had two normal children and a miscarriage previously Following the patient's birth there was a second miscarriage The mother never had an X-ray before conception of the patient nor during pregnancy The patient has a speech defect, deafness due to complete atresia of both ear canals, hypertelorism, bilateral epicanthic folds and bilateral syndactyly of second and third toes He has a history of minor motor tonic seizures (without a clonic phase) since the age of 5 years, but the electroencephalogram is normal His intelligence quotient is 53 on the basis of performance only (owing to his deafness) using the Wechsler intelligence scale for children

The majority of cells contain 46 chromosomes In every cell, one of the chromosomes in the 16–18 group is missing (probably number 18) and a ring-shaped chromosome is found in its place In most metaphase plates this chromosome appears as a monocentric ring, each ring being smaller in diameter than the length of the chromosomes in the 21–22 group However, in about 15 per cent of the cells the ring is twice the size seen in the majority of cells and appears to have two constrictions The ring structure is most clearly seen in prometaphase (Fig 2)

In both patients, all cells analysed have a ring chromosome This suggests that in man, as in *Drosophila*, the ring may be persistent Since these children do not appear to be too severely affected, especially the second case, any deletions involved in ring formation must be relatively small

The work in Winnipeg is supported by funds from the U S Public Health Service grant *RG*–7950, the U S National Foundation and a Dominion-Provincial Health grant The London (Ontario) work is supported by Mental Health grant No 605–5–287 of the National Health Grants programme of Canada

Variable Height of Intestinal Absorptive Cells

The height of absorptive cells of the small intestine is known to vary in different parts of the gut and also according to their position on the villi In paraffin sections it is seen that the cells at the tip of the villus are shorter than those along its sides However, it is not generally appreciated, particularly in paraffin sections, that even adjacent cells may vary considerably in height This becomes obvious when cells

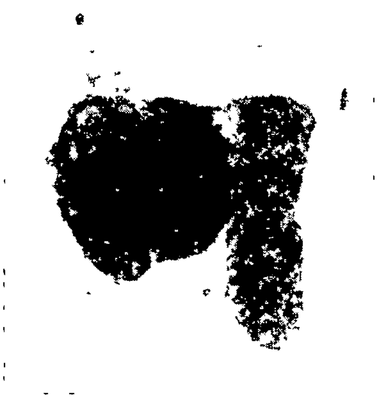

Fig 1

are studied in scrapings from fresh gut suspended in isotonic saline, Fig 1 represents a not infrequent appearance of cells of the albino rat (×1,500) The cells have been lightly stained with toluidine blue Their striated borders, terminal webs and terminal bars are in alignment The bases of all three cells reach different levels, one projecting far below the others A projecting base has also been seen in a cell in the middle of a row on other occasions The occasional bi- and tri-nucleate absorptive cells of giant size reported by me (*Acta Anat*, Basle, in the press) would also probably stand with the striated border aligned with their neighbours by having their bases sunk into pockets of basement membrane and lamina propria

Palay and Karlin[1] have shown that the cytoplasm of absorptive cells is stiffer in the microvilli and the terminal web, and adhesion of the cell membrane is firmest at the terminal bars (a rather misleading term in view of the bars seen in sections being only parts of a hoop encircling the cell) The rest of the cytoplasm has been called by these authors "a moving stream of semisolid material, which lies upon a contractile substratum", the latter comprising the lamina propria of the villus They have shown that the lateral parts of the cell membrane below the terminal bars are merely apposed and not adherent

We assume that the basement membrane and the immediately subjacent part of the lamina propria behave like a fluid cushion during life, and local deformations to accommodate cells of different heights occur as required Experimental work with cholinergic substances now in progress leads us to believe that in the living state the height of absorptive cells may show marked changes during the span of an hour But in spite of such fluctuations, the cells retain alignment in the apical region by accommodating each other along their lateral faces below the terminal bars and through the resilience of the substratum The fact that sudden variations in heights of cells are not noticeable in paraffin sections may perhaps be explained by the shrinkage of cells during preparation, and accommodation along their lateral faces while the basement membrane takes in the slack as it shrinks along with the lamina propria

VIROLOGY

A Sensitive Polarographic Test for the Detection of Protein Impurities in Viral Nucleic Acid

Recently it was shown that the polarographic method is suitable for the determination of small amounts (0 2 per cent and more) of non-virus protein in tobacco mosaic virus (TMV) preparations[1] In further experiments we have found this method equally suitable for the detection of traces of protein contaminants in the infective ribonucleic acid (RNA) preparations, isolated from TMV by the phenol method according to Gierer and Schramm[2]

A few years ago Berg[3] recommended the polarographic method for determination of protein impurities in preparations of RNA and DNA of various origin He also showed that RNA gives no polarographic wave in standard supporting electrolyte, first used by Brdička[4] for detection of proteins In trying to apply the proposed method it became evident that the polarographic method for determination of protein impurities has many restrictions (1) The method can be used only when a pure preparation of protein which is identical with the contaminating protein is available as a standard, (2) Neither the contaminating protein nor the standard must be denatured, or if so, then to the same degree, (3) When the RNA preparation is contaminated by more than one kind of protein the quantitative evaluation of the protein content is possible only in special cases In the case of infectious RNA preparations isolated from TMV by the phenol method[2] all the above requirements listed in the restrictions are satisfied The TMV particle is composed of an RNA filament of mol weight 2 million embedded in an orderly arranged aggregate of about 2,300 identical protein sub-units[5] In the course of the isolation of infectious RNA by phenol extraction, the viral protein remains in the phenol layer whence it can be easily isolated by methanol precipitation[6] This protein can serve as a suitable standard for determination of protein contamination in infectious RNA After appropriate washing the protein can be maintained in a very stable, solid form and conveniently redissolved in decimolar sodium hydroxide before use In this strong alkaline solution the protein remains in the form of its monomer (mol wt 18,000) Decimolar sodium hydroxide does not change the essential properties of the virus sub-units, when the latter are mixed in favourable conditions with infectious RNA, they reconstitute the original infective particles[6].

In our experiments the viral protein, isolated as described here, has given a very strong polarographic

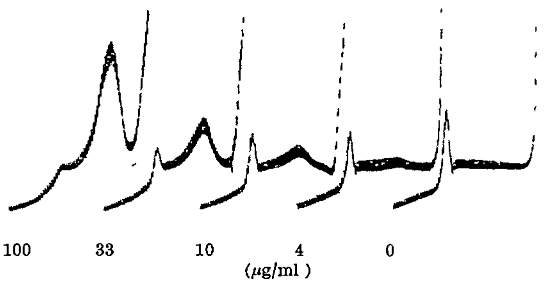

Fig 1 Polarographic records of isolated TMV protein at 0° C The final concentrations of the protein in the standard supporting electrolyte are given below the curves

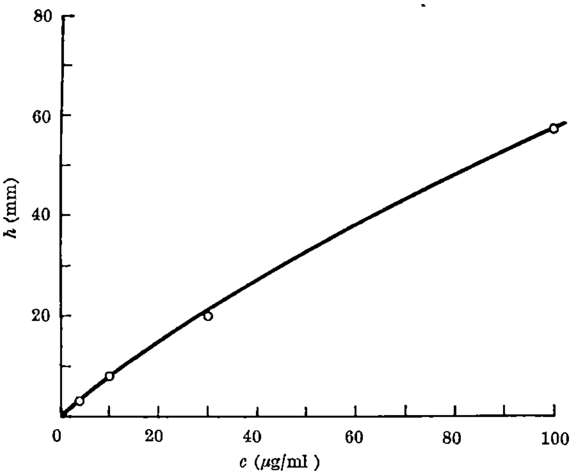

Fig 2 Height (h) of the TMV protein wave versus its concentration (c) in the standard supporting electrolyte at 0° C $h=f(c)$

reaction in ammoniacal solutions of trivalent cobalt, in contrast to RNA, which is inactive Fig 1 shows the polarographic curves of viral protein recorded at 0° C in the supporting electrolyte of the following standard composition 0 001 M $Co(NH_3)_6Cl_3$—0 1 M NH_4OH—0 1 M NH_4Cl The protein concentration decreases from left to right from 100 to 0 μg/ml , the last curve representing the pure supporting electrolyte solution As seen in Fig 1, the smallest amount of protein still detectable in the conditions used is 4 μg/ml Moreover, the sensitivity of the polarographic reaction can be appreciably increased by increasing the ammonia and cobalt concentrations in the supporting electrolyte The approximately linear relation between the height of the protein wave and protein concentration remains up to about 100 μg/ml (Fig 2)

As the groups responsible for the typical polarographic reaction of proteins are absent in RNA, the presence of the contaminating viral protein in infectious RNA preparation can be easily detected by the polarographic method The great sensitivity of this method enables the determination of as little as 0 02 per cent protein contaminant in RNA The demand for analysis is 0 1 ml of 1–2 per cent RNA solution One can use much lower concentrated RNA solutions, but then the sensitivity of the method decreases correspondingly The 0 1 ml volume is, however, not the lowest limit, with a special device it is possible to analyse even smaller amounts

For determination of traces of protein contaminant in the viral RNA preparation the following method is recommended The sample of RNA is incubated in decimolar sodium hydroxide for 1 h and then polarographed at 0° C (ref 1) in the supporting electrolyte of the following composition 0 003 M $Co(NH_3)_6Cl_3$—0 5 M NH_4OH—0 15 M NH_4Cl—0 05 M NaOH The protein content of the sample is determined by the method of standard addition The virus protein isolated from the phenol layer, as already mentioned, and dissolved in decimolar sodium hydroxide serves as a standard The linear relation between the height of the protein wave and protein concentration is valid with good approximation up to 50 μg/ml The last value safely exceeds those encountered in infectious RNA preparations isolated by phenol extraction

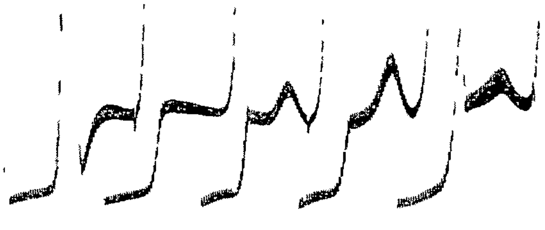

Fig 3 Determination of protein contamination in the infectious RNA preparation Concentration of RNA, 10 mg/ml , the amount of protein standard added, 0 005 mg/ml

Fig 3 shows the results of polarographic determination of protein contaminant in an infectious RNA preparation isolated from TMV by the phenol method according to Gierer and Schramm[2] The infectivity of this RNA was equal to 0 5 per cent infectivity of the intact TMV containing the same amount of RNA The evaluation of the protein content in the RNA sample was performed by the method of standard addition The first curve on Fig 3 represents the polarographic record of the supporting electrolyte alone, the second, the same but with an addition of a small amount of gelatin for suppression of cobalt maximum, the third curve shows the record of RNA preparation under test at 1 per cent concentration The polarographic wave present on this curve is due to the protein contaminant The fourth curve shows the result of the addition of 5 μg/ml TMV protein into the RNA sample The last curve represents the polarographic record of pure TMV protein in 5 μg/ml concentration The increase of the polarographic wave caused by the addition of 5 μg/ml protein standard corresponds exactly to the height due to the same amount of pure standard

Evaluation of the polarographic curves revealed 4 5 μg/ml protein in the 10 mg/ml RNA sample tested This corresponds to 0 045 per cent protein in the infectious RNA preparation Such a small amount of protein can scarcely play any part in the process of infection by the RNA preparation For maintaining the infectivity in the case of TMV RNA the integrity of the whole 2 million mol RNA macromolecule is necessary[7] Association of one 18,000 mol wt protein sub-unit with each RNA molecule would give a protein contamination of about 1 per cent The contamination actually found in our experiments was more than 20 times less As in repeated phenol extraction the infectivity of the RNA preparation does not drop, and as there is no reason for assuming the existence of a certain portion of phenol-resistant particles in the virus population, the role of a whole protein sub-unit in the process of infection must be excluded The method described cannot help us to exclude a similar role of polypeptide fragments of lower mol wt , although such form of their activity is very improbable

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned

Assistant Experimental Officer (with experience of general laboratory techniques and equipment, and preferably a knowledge of gas chromatography and an interest in instrumentation and electronics) in the Biochemistry Department—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge (August 25)

Temporary Lecturer in the Department of Medicine—The Registrar, The University, Liverpool, quoting Ref No CV/154/N (August 25)

Senior Technical Officer (with a degree with botany or agricultural botany as a major subject) in the Official Seed Testing Station—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (August 27)

Assistant Lecturer (graduate) in Dairying—The Registrar, University College of Wales, Aberystwyth (August 31)

Assistant Lecturer (graduate in physical metallurgy or solid state physics, and preferably with an interest or research experience in the field of deformation studies or magnetic properties) in the Department of Metallurgy—The Registrar, The University Manchester 13 (August 31)

Leverhulme Student (with a postgraduate diploma in chemical engineering or equivalent qualifications) in Chemical Engineering—The Registrar, King's College (University of London) Strand, London, W C 2 (August 31)

Research Assistant in Sociology in the Department of Social Studies—The Registrar, The University, Hull (August 31)

Tutorial Student (graduate or about to graduate) in Zoology—The Registrar, King's College (University of London), Strand, London, W C 2 (August 31)

Assistant Lecturer (preferably with experience of research and teaching) in the Department of Pharmacology—Clerk to the Council, School of Pharmacy, 29/39 Brunswick Square, London, W C 1 (September 1)

Research Assistant in Dermatology—The Secretary of University Court, The University, Glasgow (September 1)

Senior Lecturer (preferably with a Ph D degree and suitable experience in electronics) in Electronic Physics, and a Lecturer in Electrical Engineering—The Secretary, University of St Andrews, Queen's College, Dundee (September 1)

Assistant Lecturer (with research interests in the mode of action of hormones at the cellular level, and qualifications and/or experience should include biochemistry or biophysics) in Zoology—The Registrar, The University, Sheffield (September 3)

Research Demonstrator in the Department of Metallurgy—The Registrar, The University College of South Wales and Monmouthshire, Cathays Park, Cardiff (September 6)

Research Fellow in the Nuclear Physics Group of the Department of Physics, to prepare and participate in experiments on the 7 GeV proton synchroton at the Rutherford High Energy Laboratory of the National Institute for Research in Nuclear Science—The Registrar, Queen Mary College (University of London), Mile End Road, London, E 1 (September 7)

Senior Lecturer or Lecturer (veterinary surgeon) in Veterinary Medicine, for duty at the field station near Potters Bar, Middlesex, and at Camden Town—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N W 1 (September 7)

Assistant Librarian (with a good honours degree)—The Registrar, Queen Mary College (University of London), Mile End Road, London, E 1 (September 8)

Demonstrator (medically qualified, and/or an honours degree in physiology) in the Department of Physiology—The Registrar, The University, Leeds 2 (September 10)

Entomologist (with a good honours degree), to study the effects of insect infestations on the growth and yield of crop plants—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 10)

Lecturer in Anthropology at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W 1 (London and New Zealand, September 15)

Staff Tutor (with a special interest in field work) in the Biological Sciences in the Department of Extra-Mural Studies—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (September 15)

Technical Officer (with a good honours degree or equivalent qualifications in electrical, electronic or radio engineering or another approved subject) in the Department of Biochemistry—The Secretary of the Faculty Board of Biology B, Department of Anatomy, The University, Downing Street, Cambridge (September 15)

Chair of Physiology in the University of The West Indies—The Academic Registrar, University of London, Senate House, London, W C 1 (September 17)

Senior Lecturer or Lecturer (preferably with experience in teaching physical geography) in Geography at the Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1 (Australia and London, September 24)

Professor of Biochemistry—The Dean, Faculty of Science, Hebrew University of Jerusalem, Israel (September 25)

Chair of Chemistry (inorganic or physical) in the University of Queensland, Brisbane, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1 (London and Brisbane September 30)

Chair of Zoology—The Secretary, The University, Edinburgh (September 30)

Lecturer in Geology at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1 (New Zealand and London September 30)

Lecturer (preferably with experience in invertebrate teaching to B Sc honours level) in Zoology at the University of Cape Town—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall London, S W 1, and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (September 30)

Regius Chair of Forensic Medicine in the University of Glasgow—The Private Secretary, Secretary of State for Scotland, St Andrew's House, Edinburgh 1 (September 30)

Lecturers and Senior Lecturers in Electrical Engineering at Monash University, Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office) Marlborough House, Pall Mall, London, S W 1 (Australia and London October 8)

Chair of Pathology in the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall London, S W 1 (New Zealand and London, October 15)

Chair of Biology in the School of Biological Sciences—The Registrar, University of East Anglia, 4 Cathedral Close, Norwich NOR 16P (October 31)

Assistant Experimental Officer/Experimental Officer (unestablished) (with G C E "A" level in two scientific subjects (one biological) or H.N.C., or pass degree or equivalent or Fellow of the Institute of Medical Laboratory Technology, and preferably an elementary knowledge of physics) at the Microbiological Research Establishment (War Dept), Porton Down, near Salisbury, for work in the Biophysics Section of factors influencing survival of air-borne micro-organisms—C13A(ii), War Office, London, S W 1

D S I R Research Fellow (with a Ph D or equivalent qualification in applied mathematics or theoretical physics, and experience in the use of digital computers) in Theoretical Seismology in the Department of Astronomy—The Secretary, The University, Edinburgh

Senior Lecturer or Lecturer (with a first- or second-class honours degree or equivalent, together with at least two years experience in teaching, industry or in research establishments, and preferably special experience in the field of the theory of mechanics or machines) in Mechanical Engineering—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire

Senior Scientific Officer (physical chemist, with a first- or second-class honours degree in chemistry and at least three years postgraduate experience, and experienced in handling materials at very low concentrations, for example, a few microgrammes per cubic metre) to investigate the reactions of atmospheric pollutions and their effects on the formation of mists—The Director, Warren Spring Laboratory, D S I R , Stevenage, Herts, quoting Ref WSL 22Z

THE SPACE GAME

FOUR Russians are now known to have travelled in pre-determined orbits around the Earth. Gagarin was the first to complete one orbit, Titov covered seventeen. Now, on August 15, the next two astronauts have returned safely to Earth, one (Major Andrian Nikolayev) having completed sixty-four orbits, and the other (Lieut.-Colonel Pavel Popovich), forty-eight.

The Prime Minister of Great Britain and the President of the United States of America have already sent messages of congratulation to the Prime Minister of the U.S.S.R. No doubt political leaders of other countries have sent, or will be sending, similar messages. Such congratulations are very well merited, and *Nature* now wishes, on behalf of the whole world of science, to extend its congratulations to the Soviet scientists and technologists who made possible this most recent epic flight. We also express our admiration of both Major Nikolayev and Lieut.-Colonel Popovich for their bravery and devotion to duty.

It is a pity, therefore, that *Nature*, which publishes important research contributions on all scientific subjects (from space science and astrophysics to virology and macromolecular biology) submitted from every country in the world, and which is also read in every part of the world where scientific research, advancement and teaching are going on, is able at this stage to publish only two short paragraphs (p. 755 of this issue) which refer to the latest Russian achievement and which, though written by one of Britain's leading authorities on the subject, can be of special interest to scientists. It is significant that all the rest of the news concerning this event has already appeared through the media of newspapers, television or radio—no doubt, not before severe scrutiny and censorship.

The Soviet scientists (with the practical collaboration of Nikolayev and Popovich) have proved that they have made great strides recently in scientific and technical research. Nevertheless, the first immediate announcement that the two astronauts are to receive the highest Soviet awards as *sportsmen* gives the keynote to the world's attitude and reaction to this great feat—for the world looks on it as a game: a game in space. Sportsmen play games, and games involve competition. Players compete against their opponents.

This latest achievement in space gives some points and honours to the Soviet scientists and technicians. They have, for example, been the first to prove that man can live, work and sleep in apparent weightlessness for days on end, they have been the first to present live television pictures of a man while in orbit, they have been the first to establish radio communication between two men while both are in space, they have been the first to produce a double descent from orbit. But the Russians were not the first to adopt the policy of keeping the world informed of their space activities—failures as well as successes. The credit, and a very important credit, for that must be given to the United States.

Yet, what has world reaction been? We have so far heard or read little about this feat as a *scientific* achievement—yet, fundamentally, it is just that. On the other hand, it is being looked on as a game in which, for the time being, some points go in favour of the U.S.S.R. But that is as far as the analogy goes: for there is no referee, and even the world of onlookers can see only a very small part of this vast arena—and even this is decided by the players or their sponsors of one side only. So politics are already in the picture: those in favour of the communist way of life are meanwhile in various ways expressing their joy, whereas some (though not all) others, in the democratic countries (especially those who have had no training in science and cannot understand its objectives), have betrayed a feeling of jealousy or what is known colloquially as 'sour grapes'.

We cannot afford to ignore this world reaction: we laugh at it at our peril. It all takes us back to the many occasions when *Nature* has warned that it will be an evil day if science ever becomes the tool of diplomatic or political intrigue. Yet that day has now come. Too often do we hear of the need for space research for reasons of prestige—that is, *political* prestige, of course, and among most of us, this means priority—to be the first: yet priority does not bring prestige in the long run. Moreover, it is already accepted by the layman that the most scientifically advanced country is the one which will win the next world war. Thanks to science, another all-out world war was rendered unthinkable long before the first human astronaut went into orbit: hydrogen bombs, research with rockets, etc., have ensured this. More than one country, and not just two, are already in a position practically to destroy the world as we know it, or would wish it to be.

Therefore, although we agree with Sir Bernard Lovell, director of the Jodrell Bank Experimental Station, that it now appears that the Russians are at present masters of space in the military sense, and although we must reiterate our admiration for the Russian scientists in this, their latest, achievement, we cannot accept the idea that the Russians have necessarily taken the lead in this space game. There are far too many facets, hundreds of ways in which space research can be, and undoubtedly is being, carried out, and, therefore, many, many ways in which points can be gained or lost in this competition. There is every reason for believing that the Americans have the lead in certain aspects of space research, as was emphasized in our comments on the great achievement of Colonel John Glenn (*Nature*, 193, 807, 1962). Unfortunately, in our opinion, international politics have intervened in science and, in certain respects, seem to be in control The result is that scientists in one country are left guessing at what their colleagues in another country are doing, mainly because their political superiors maintain the right to decide what shall be published and what shall be considered secret or, to use the modern phrase, 'classified' Readers of *Nature* would probably be amazed at the delay in publication of certain communications (mainly from the Government departments of some countries) in practically all branches of science, merely because a Government official (usually non-scientific) must have the last word, and often takes a long time in saying it In the long run, this cannot be to the advantage of science, so eventually there lies the threat to world peace, because no one can effectively control that which he cannot understand

These views have been expressed many times in the columns of *Nature* Competition in the search for knowledge cannot be healthy, collaboration can This belief has now been stated more explicitly by General Eisenhower in his comments on the latest scientific achievement of Soviet Russia He does not believe that the Russians have the lead in space He quite rightly objects to the word 'gap' in this connexion He believes that the two countries—the U S S R and the U S A—have been working along different lines We entirely support General Eisenhower, and especially when he said "Co-operation in space research between Russia and America would be a fine thing" Sir Bernard Lovell was even more forthright, when he said that "More than ever, one is appalled by the foolishness of these two countries attempting a common problem in competition"

Indeed, it should not be left at that Collaboration between the U S S R and the U S A would be excellent, but better still would be universal collaboration among the scientists of the world, for there are first-class men of science in many countries Throughout her history, for example, Great Britain has had, and still has, every cause for pride in her scientific achievements, and this applies to some other countries as well So spectacular has space research now become, however, that the general public seem to be looking on it as the prerogative of the U S S R and the U S A It is about time that this view was challenged, for it is not true

Referring to the magnificent results recently obtained by the Soviet scientists, through the agency of Major Nikolayev and Lieut -Colonel Popovich, Prof Alexander Topchiev, vice-president of the Soviet Academy of Sciences, said "The Earth's environment up to 300 kilometres from its surface has been turned from a belt of the unknown into a huge laboratory" So be it—a research laboratory No scientist, no matter what his political views, could possibly imagine a research laboratory without team work A laboratory is certainly not a games arena where sportsmen vie with each other it is a place where men and women foregather in a search for knowledge, a seeking after the truth, and this by experiment and above all, by free discussion of methods and results without interference from those who cannot be expected to know much, if anything, about science or its objectives This is not an argument in favour of complete freedom for scientists to do just as they like without reference to other members of the community in which they live, especially the elected leaders of such a community: but it is a plea for scientists to be allowed much more freedom to communicate and collaborate with each other (recognizing especially that the discipline of science, like the arts, music and so forth, cannot acknowledge political frontiers) If this could be conceded, then, at least, two stumbling-blocks to world advancement would be removed—the astronomical waste of State funds because one country must often be repeating what another has already done, and the very grave prostitution of some of the sciences (not only space research) to political aims and objectives

BRITISH PROSOBRANCHS

British Prosobranch Molluscs

Their Functional Anatomy and Ecology By Vera Fretter and Alastair Graham (Publication No 144) Pp xvi+755 (London Ray Society, 1962 Sold by Bernard Quaritch, Ltd , 11 Grafton Street, London, W 1) 168*s*

THE key to the understanding of the Mollusca resides in the prosobranch Gastropoda If *Neopilina* represents primitive molluscan structure, as it probably does, then great secondary simplification preceded the spectacular evolutionary radiation which gave rise to the major molluscan classes The nearest approach to these simplified molluscs are the more primitive archæogastropod prosobranchs, separated from them only by torsion and possibly asymmetrical coiling

In their account of the British Prosobranchia, Dr Vera Fretter and Prof A Graham have given by far the best general account ever written of this most informative of all molluscan groups, in which basic simplicity leads on to a range of adaptive radiation unsurpassed in any corresponding group in the entire animal kingdom The authors are little concerned with taxonomy and only to a minor degree with the shell, indeed, the majority of their species are figured without the shell and with the 'soft parts', it must appear to the conchologist, almost indecently exposed As stated in its sub-title, this book is concerned with "Functional Morphology and Ecology". To this extent it represents something of a new and welcome departure in publications by the Ray Society and one which, in the hands of its uniquely qualified authors, is an overwhelming success

We are carried in the course of some 700 pages, with more than 300 admirable figures, from an introductory account of the Mollusca followed by a general description of *Littorina littorea* as a typical, as well as probably the commonest, British prosobranch, through sixteen chapters dealing with functional morphology, from shell and mantle cavity to reproductive system and the formation of spawn—in which the mesogastropods show such fascinating diversity—followed by descriptions of development and of larval forms All is covered with a precision of wording only equalled by the elegance of the accompanying figures One is initially surprised that so much is known about these prosobranchs, but realization follows that although every source of published knowledge, including the major contributions of the two authors and their pupils, has been utilized, yet a notable proportion of this book, including very many of the illustrations, consists of hitherto unpublished observations

The third section of the book deals with ecology and is concerned with the limpets, whelks and tingle and other prosobranchs of rocky shores, with those of other marine habitats, with prosobranch inhabitants of brackish and fresh-waters and of the land, and finally with the parasites of these animals It is our good fortune that the very occasional appearance of the heteropod *Carinaria* and more frequent appearance of *Ianthina* brings both these pelagic molluscs within the British fauna and so within the scope and detailed description of these authors We are also fortunate in possessing an interesting range of estuarine and fresh-water prosobranchs and even two terrestrial species, one of which the apple shell, *Pomatias*, receives particular and most welcome attention

It is only in the Neritacea that the British fauna, with its solitary fresh-water representative, *Theodoxus*, is seriously lacking The presence of some of the marine and terrestrial representatives so abundant in warmer latitudes would have been welcome because of the treatment they would here have received with perhaps the conclusion that these animals should be removed from the Archæogastropoda (or Diotocardia, as here preferred) to constitute an order of similar standing to the Mesogastropoda (Monotocardia)

The final section deals with relationships of the Prosobranchia with an appendix on classification and another containing a habitat and distribution list This is followed by 37 pages of references

No comparable book on the Mollusca has been published in our time (Thiele's great hand-book is in a different category) This is functional morphology at its best Every malacologist in every country—because its scope far transcends the British fauna—should possess this book It is infinitely revealing in its descriptions of the elaborate intricacy, above all in the buccal and deeper alimentary systems and in the reproductive system, with their remarkable evolutionary developments

I have read carefully through this very long book and find no cause for significant criticism and only one mistake—a reference on page 10 to cuttlefish where octopods are clearly meant C M YONGE

THE COMPANY OF MINERAL AND BATTERY WORKS

Elizabethan Monopolies

The History of the Company of Mineral and Battery Works from 1565 to 1604 By Prof M B Donald Pp xv+256+10 plates (Edinburgh and London Oliver and Boyd, Ltd , 1961) 50*s* net

THE introduction of a new source of power has always resulted in technical advances, but the changeover inevitably involves the design and manufacture of the necessary machinery the cost of which implies the raising of adequate capital The sixteenth century was such a time of marked development in the utilization of water-power, particularly in the mechanisms necessary for its conversion to industrial use in, for example, providing the air blast for furnaces, operating stamp mills for the crushing of ore or in pumping water from the mines themselves

The capital required ultimately reached proportions so high as no longer to be within the scope of the individual, and associations of a number of persons became essential Two such partnership companies were formed in Elizabethan England, both concerned with the manufacture of metals and the products produced from them Both the Company of Mines Royal and the Company of Mineral and Battery Works received their royal charters in 1568, and it is with the second, and smaller, of these that the present work is mainly concerned Unlike the Mines Royal, the capital was raised entirely in Great Britain, and whereas that body was concerned chiefly with the production of copper in Cumberland, the Mineral and Battery Works had three fields of interest—lead in north Derbyshire, iron, largely for the production of wire, near Tintern Abbey, and brass at Isleworth in Middlesex This range of activity proved too extensive to be controlled by any one of those concerned, and this, together with the technical failure at first to produce brass of sufficient ductility to be 'battered' into the required shapes, rendered it easier to run the partnership as a licensing company drawing its income from royalties paid by licensees operating the processes for which the Company held patents

Since the formation and development of these two Companies are the roots of all future company law and procedure—and not only in Great Britain—the main emphasis of Prof Donald's book is on the legal and commercial sides, though there are inevitably excursions into the technology of the time which add to our knowledge of the history of metallurgy in England and Wales at a critical period in its development

The story is one of continual quarrels and law-suits which later played no small part in restraining the Royal prerogative to grant monopolies and patents It is a story well worth telling, and it is well told, though one would like the evidence for the statements on page 96 that at that date "The phosphorus content" of iron "could be controlled by using limestone to give a basic slag to remove it as phosphate" and that "The sulphur content was controlled by selecting ores containing manganese " F C THOMPSON

HIPPED-PLATE AND THIN SHELL STRUCTURES IN ENGINEERING

Hipped-Plate (Folded Plate) Structures

Their Theory and Analysis By Joachim Born Translated by C V Amerongen Pp ix+250 (London Crosby Lockwood and Son, Ltd , 1962) 63*s* net

Theory of Elastic Thin Shells

By A L Gol'denveizer Translated from the Russian and edited by G Herrmann (International Series of Monographs on Aeronautics and Astronautics Division I Solid and Structural Mechanics, Vol 2) Pp xxi+658 (London and New York Pergamon Press, 1961) 105*s* net

THE literature on hipped-plate or folded-plate structures, as such, is not very extensive although, in recent years, quite a number of papers have appeared in the technical press The book by Born is, therefore, welcome in that it presents a thorough study of what is a specialized branch of structural engineering

The first part of the book deals with the analysis of prismatic hipped-plate structures Initially, the analysis is based on the assumption that the junctions of the plates are laterally restrained which leads to the so-called equation of three shears or stresses This equation is then expressed in differential form to enable the deformations at the junctions to be taken into account where warranted These analyses are then applied to continuous structures, to study the effect of transverse diaphragms and edge beams and, in fact, to the practical problems arising in hipped-plate structures

The second part of the book discusses the various flexural theories that have been put forward and shows how these may be applied to practical designs to determine both the 'membrane' and the bending stresses

Both these parts are illustrated by numerous examples which emphasize the essential features of each method of analysis considered and, further, show how the calculations should be performed in the design office in the most rational and economical manner

The final part of the book deals with pyramidal hipped-plate structures of various types, the fundamental structural action of the various types is broken down into the relevant slab components and analyses developed appropriate to a wide range of structures Also in this part of the book, some interesting structural problems are discussed in the light of hipped-plate theory, among these are plate girder bridges, spiral staircases and various torsion problems

The presentation of the material in the book is in the form of a large number of short chapters, each dealing with a specific aspect, this makes for easy reference In general, the figures are clear, but on some the reduction in size has been such as to make reading of numerical data and some of the symbols difficult

The book is written from the point of view of a structural designer rather than that of the mathematical analyst, the examples chosen are admirably suited to emphasize the design aspects of each problem and the most suitable method of dealing with these The author is a consulting engineer and his book can certainly be recommended to others in this profession and to students seeking a fundamental appreciation of hipped-plate structures

The book by Gol'denveizer is a mathematical treatise on the elastic theory of thin shells which, to a certain extent, is complementary to those already published by Vlasov and Novozhilov The first part of the book presents in detail the derivation of the complete fundamental equations for shells using vector notation This section is based on the assumption that plane sections remain plane, which Gol'denveizer states as "the preservation of the normal element", this assumption is discussed in some detail and the implications of it are illustrated with reference to the equations derived earlier

Part 2 of the book considers the membrane theory for shells as an approximation to the equations derived in Part 1 resulting from the assumption that the transverse shear forces and the twisting moments are zero Thus, the membrane theory is treated as an approximation to the more general bending theory and its range of applicability as such is considered

Part 3 deals with the problem of circular cylindrical shells using Fourier series, the main purpose of this study is to emphasize those aspects of approximate analytical methods of interest in more complex shell structures and to enable the implications of the various assumptions in the analyses to be considered

Part 4 is largely a mathematical justification of the various approximate methods using what is called asymptotic integration In this section the higher derivatives of a parameter representing the half thickness of the shell are retained and attempts made to carry out the integration with complete mathematical rigour The final part of the book deals with the derivation of suitable approximate methods for various types of shell structure

This book is reproduced by a photolithographic process which is quite acceptable to the reader, despite its lack of uniformity It is to be regarded as a treatise on shell theory and its usefulness will be primarily to the research worker in this specific field

R E Rowe

MAGNETIC RESONANCE SPECTROSCOPY

NMR and EPR Spectroscopy

Papers presented at Varian's Third Annual Workshop on Nuclear Magnetic Resonance and Electron Paramagnetic Resonance, held at Palo Alto, California By the NMR–EPR Staff of Varian Associates Pp viii+288 (London and New York Pergamon Press, 1960) 80*s* net

It has become an annual practice of Varian Associates to hold a 'workshop' at Palo Alto, California, and a similar meeting is to be held at Zurich later this year The 'workshop' is designed to introduce new workers to the characteristics of nuclear magnetic resonance and electron paramagnetic resonance phenomena, and to keep experienced ones abreast of developments in both fields The 1959 meeting was divided into three parts an introductory session, two days of lectures and laboratory sessions devoted to high-resolution nuclear magnetic resonance spectroscopy, and similarly, two days to electron paramagnetic resonance spectroscopy

The book is essentially a record of these lectures and some of the laboratory sessions, its aim and general arrangement follow the pattern set by the 'workshop' Part 1 contains five chapters which provide an initial survey, outlines of the basis and range of application of nuclear magnetic resonance and electron paramagnetic resonance spectrometers respectively, and then descriptions of their operating fundamentals Part 2 describes the theory and instrumentation involved in high-resolution nuclear magnetic resonance spectroscopy, and some structural and chemical applications, followed by brief accounts of more specialized topics including the determination of relaxation times, the measurement of the radio-frequency field, and the use of magnetic field modulation in integrating systems Part 3 similarly gives a more detailed account of electron resonance spectroscopy, its chemical and biological applications, and its use for photochemical studies, together with short discussions of colour centres and double resonance phenomena

The book therefore, gives a survey of many aspects of nuclear and electron resonance spectroscopy, although there are some important omissions, for example, there is no discussion of the use of nuclear magnetic resonance for the structural analysis of solid samples Considerable space is devoted to the influence of various instrumental parameters on the output signal, and while this is largely described around Varian instruments, most of it will be relevant to other spectrometers The main defect is an apparent lack of editing and co-ordination in producing the book from the material presented at the 'workshop', the repetition which is acceptable and desirable in a lecture series is less welcome in a book Basic topics are described with increasing detail but with considerable overlap on passing through the various chapters of Part 1 to Parts 2 and 3, and, for example, the same photograph of a high-resolution nuclear magnetic resonance spectrometer appears three times in Part 1, and similar drawings of the spectral shape produced by 'dished' and 'domed' magnetic fields occur on pp 60 and 95

In short, the book contains good material but is badly edited It can be recommended to all who need a general introduction to the field, and should be particularly valuable to those who want some insight into the experimental problems involved in the operation of spectrometers R K WEBSTER

DEEP-SEA MICROBIOLOGY

Meeres-Mikrobiologie

Tiefseeforschungen Von Prof Dr A E Kriss Pp ix + 570 (Jena Gustav Fischer Verlag, 1961) 98 10 D M

It has long been recognized that Russian investigators have played an important part in the development of the science of marine microbiology It is unfortunate, however, that owing to language difficulties and the relative inaccessibility of many of their journals and monographs, their results have remained comparatively unknown to most workers outside the U S S R The appearance of another book on marine, and in particular on deep-sea, microbiology where so few already exist would in itself be an event, but where it also summarizes the tremendous volume of recent Russian work in this field it is doubly welcome The present volume is a revised German edition of the 1959 Russian one which gained for its author a Stalin prize A more thoroughly revised English version is due to appear shortly

In 1947 the Institute of Microbiology of the Academy of Sciences of the U S S R organized a series of investigations into the microbiology of the deep layers of the various seas and oceans This was in contradistinction to most of the previous work, both inside and outside the U S S R , which dealt mainly with surface waters and the continental shelf, and which was so ably summarized by ZoBell in his *Marine Microbiology* (1947) Commencing with the Black Sea, these Russian investigations have virtually covered every major sea and ocean from the Arctic to the Antarctic, allowing comparison to be made between various types of marine basins—the Black Sea, an intra-continental deep-sea basin, the Caspian, the largest sea-lake, the Pacific, in regions containing the deepest trenches in the world, the Arctic, with its perennial covering of pack ice and the results to date have now been ably summarized by Prof Kriss

Descriptions are given of the methods, both quantitative and qualitative, used for investigating water masses in depth including two pioneered in this sphere by Kriss and his colleagues, namely, the submerged-slide and membrane-filter techniques As a result, we have for once a composite picture of the vertical and horizontal distribution of bacterial populations throughout the world's seas and oceans, including the effects thereon of various seasonal, geographical and other factors Two long chapters are devoted to descriptions of the various species of bacteria, yeasts and actinomycetes encountered and their morphological variations, both vertical and horizontal Some of these organisms are new to science, for example, the class of Krassilnikoviae, of which some excellent microphotographs are provided

Having described both qualitatively and quantitatively the microflora, and also their general biochemical propensities in transforming a great variety of substances in sea and oceans, Kriss then attempts to give some idea of the microbial biomass in these water basins, utilizing to the full the direct-count and membrane-filter techniques, although some may doubt the reliance placed on these by Russian workers Data indicate that the greatest microbial concentrations occur in certain layers in the Caspian Sea (approximately 250,000/ml or a biomass of 45 mgm /m ^{3}) followed by the Black Sea and the Pacific in the area of the Kuril Islands In the North Polar Sea, even at the season of maximal activity the counts and biomass are approximately only 1/10–1/20 of those of the Caspian

To many readers, the final chapters on micro-organisms in relation to the biological productivity of the ocean, and as indicators of hydrological phenomena, will be of most interest Kriss maintains that insufficient account has been taken of the importance of micro-organisms for investigating problems of biological activity in aquatic environments, as, for example, in their role in providing, in themselves, food for young fish and in producing vitamins and other biologically active substances With regard to the use of micro-organisms as hydrological indicators, Kriss obviously believes that they can be of immense value for the study of the dynamics and origin of water masses and for indicating deep currents at present poorly defined by other methods By the use of micro-organisms, Kriss has been able to substantiate and extend the more widely accepted views concerning the general hydrography of world oceans as expounded by Sverdrup, Johnson and Fleming (*The Oceans, Their Physics, Chemistry and General Biology* New York, 1942), although on occasions he has seemed to differ considerably from these experts

In a volume such as this, full of interesting and often arresting facts and information in almost every page, it is difficult to be critical The major fault appears to be the almost superabundance of data, so that one cannot see the wood for the trees There appears to be a reiteration of material in different chapters The long, detailed Chapter 3, describing the biochemical, morphological and other properties of the various species isolated, seems out of place in this type of book, and could well have been combined with Chapter 6, also dealing with the morphological characteristics of micro-organisms Moreover, it is unfortunate that Krassilnikov's *Determinative Key for Bacteria and Actinomycetes* (Moscow, 1949), known to few outside the U S S R , should have been used for purposes of classification

Despite these criticisms, the book should be read by all interested in marine science, because none by previous authors contains anything approaching the amount of data collected here It is well produced and fully documented, and lavishly illustrated with figures, diagrams and photographs, and deserves to become widely known J M SHEWAN

INTERATOMIC FORCES: MAXWELL TO SCHRODINGER*

By PROF C A COULSON, F.R S.

Mathematical Institute, University of Oxford

(1) Introduction

CLERK MAXWELL played a notable part in the early stages of our theory of interatomic forces It is not true, however, that he initiated the kinetic theory of gases, in which interatomic forces play an essential part What he did was to extend and consolidate this field So this account is divided into two halves In the first half I will try to describe the way in which, a hundred years ago, people were thinking about the kinetic theory of gases—the kind of progress that Maxwell and others were able to make, the difficulties that they had to face, and the problems which seemed to them insuperable This will naturally lead to the second half, in which I shall show all the major problems which could not then be solved, now have been solved We shall find that although there was one direction in which, if he had been able to improve on current accuracy of measurement, further progress could have been made, in the other directions no progress was indeed possible until other new and fundamental concepts and techniques had been developed Maxwell had almost got to the limit of what he could have done in the discussion of interatomic forces We needed the quantum theory, with its many ramifications, before one could go any farther

(2) Early Ideas on the Kinetic Theory

It is hard for us, now, to realize the difficulties in developing the kinetic theory A hundred years ago even the idea of an atom was not universally recognized Indeed, as the celebrated debate involving Ostwald, Boltzmann and others showed, distinguished men of science continued for several more years to deny its existence Maxwell himself, in his famous article on the atom in the *Encyclopœdia Britannica*, begins with the definition "The atom is indivisible", and justifies this with reference to its etymological origin in the Greek, and the comment that although space and time appear to be infinitely divisible, the same is not true of the elementary units of matter But he makes little attempt, at first, to say more precisely what these indivisible units actually are

We all know that the idea of an atomic theory has a very long history, going back to Lucretius, Leucippus and Democritus But although Democritus, in a moment of vision, could say that beyond the atoms everything else was void, and although Lucretius tried to relate the smoothness or roughness of their exterior to their taste (sweetness or sourness), and although Plato with his love of symmetry spoke of their geometrical shapes (the cube, the tetrahedron, etc), it was not for many centuries that any serious progress was made Herapath (1790–1868) and J J Waterston (1811–83) had thought of collisions between the atoms, and in fact it was Waterston, himself a keen billiards player, who introduced the idea of a hard, or 'billiards ball' atom This particular idea was to play a large part in the development of the theory of gases, and it illustrates the general theorem, that the initial development of scientific ideas (though not necessarily their final form) owes more than is sometimes supposed to non-scientific factors It was suggested on one occasion, I think by Lord Rayleigh, that if Maxwell and Clausius and others had also been billiards fans, we might have seen more rapid progress in the early stages of the theory

So it came about that in 1859 when the British Association met in his own city of Aberdeen Maxwell read a paper in which he began by saying that a gas consists of many little aggregates, not yet to be closely defined, moving in all directions Up to this date it had apparently been assumed, by Clausius and others, that as these minute particles flew around in all directions, they maintained always the same uniform speed But Maxwell thought otherwise There must be some sort of distribution function At present it was unknown, but shortly it was to be discovered To quote from that first paper

> "In order to lay the foundation of such investigations on strict mechanical principles, I shall demonstrate the laws of motion of an indefinite number of small, hard and perfectly elastic spheres acting on one another only during impact
>
> "If the properties of such a system of bodies are found to correspond to those of gases, an important physical analogy will be established, which may lead to more accurate knowledge of the properties of matter"

The time was now ripe for a more careful discussion of this velocity distribution But before it could be worked out, it was evident that the hard billiards ball analogy would have to be abandoned For if two equal and perfectly elastic spheres collide not only is the total energy conserved (as it obviously must be), but the two spheres merely exchange velocities along their line of centres Furthermore, the number of collisions which result in a given deflexion will be directly proportional to the velocity This leads to an unsatisfactory variation of the coefficient of viscosity with temperature It had therefore to be modified So in 1866 we have Maxwell's most classical memoir devoted to this topic Let us see how he begins

> "In the present paper I propose to consider the molecules of a gas not as elastic spheres of definite radius, but as small bodies or groups of smaller molecules repelling each other with a force whose direction always passes very nearly through the centres of gravity of the molecules, and whose magnitude is represented very nearly by some function of the distance of the centres of gravity I have made this modification of the theory in consequence of my experiments on the viscosity of air at different temperatures, and I have deduced from these experiments that the repulsion is inversely as the fifth power of the distance

---

* The substance of one of the lectures delivered at King's College, London, to mark the centenary of the publication of Clerk Maxwell's papers on electromagnetic radiation These lectures will be published in book form

> "If we suppose the molecules hard elastic bodies, the numbers of collisions of a given kind will be proportional to the velocity, but if we suppose them centres of force, the angle of deflection will be smaller when the velocity is greater, and if the force is inversely as the fifth power of the distance, the number of deflections of a given kind will be independent of the velocity Hence I have adopted this law in making my calculations"

It sounds very good, and it is certainly attractive But alas, even though it be almost an act of impiety, truth requires us to add that not only was there a slip in the calculations, his experimental values for the variation of viscosity with temperature were also wrong So we can see that, whatever Maxwell may have thought, it was purely a fortuitous situation that led him to propose an inverse fifth power law, and then to proceed with a series of further calculations based on that assumption

The possibility of some sort of power law for the mutual attraction or repulsion of two atoms was not unthought of before this time Maxwell himself, in his *Encyclopædia Britannica* article, refers to the ideas of Boscovich, who supposed the atoms to be of zero size—mere centres of some sort of force-field—such that there was an r^{-2} attractive force down to some minimum distance $r_{\min}$, and then at closer distances an infinite repulsion But this was rejected on the grounds that atoms were not of zero size, and an r^{-2} attraction did not fit observations of the viscosity–temperature relation

This same memoir (the '*Phil Trans* Memoir', as it has sometimes been called) goes on to consider the results that would follow from the assumption of a distribution law of velocities It has about it an almost Euclidean character, as theorem follows theorem with impeccable correctness But by far the most important of these is the first derivation of the distribution law Assuming the independence of the three components ξ, η, ζ of the molecular velocity in three mutually perpendicular directions, it follows quite simply that if the distributions of ξ, η, ζ are each of the form $f(\xi^2)d\xi$, then

$$f(\xi^2) = Ae^{-m\xi^2/2kT}$$

where T is the absolute temperature A knowledge of f, now quite properly called the Maxwell–Boltzmann distribution function, enabled Maxwell to calculate all the necessary mean and relative velocities which were involved in his earlier general formulæ The essentials of the kinetic theory of gases had now been established

(3) Problems raised by Maxwell's Work

Having briefly outlined Maxwell's successes, it may be appropriate to turn to the difficulties which he exposed, and the nature of the problems which he left unsolved

First there is the word 'molecule' itself As one of the earlier quotations shows he could not decide what sort of aggregate a molecule could represent In a lecture to the British Association at Bradford he realizes some of these problems

> "But we must now go on to molecules Molecule is a modern word It does not occur in Johnson's Dictionary The ideas it embodies are those belonging to modern chemistry"

A little earlier in the same lecture

> "An atom is a body which cannot be cut in two A molecule is the smallest possible portion of a particular substance No one has ever seen or handled a single molecule Molecular science, therefore, is one of those branches of science which deal with things invisible and imperceptible by our senses, and which cannot be subjected to direct experiment"

One might almost say that he had become involved in the positivist, or operational, controversy that was to become effective some decades later In another British Association address he remarks that mathematics "is an operation of the mind", and physics is "a dance of molecules", with "laws of their own' But the connexion between the two takes us to a region where it is dangerous to tread

> "But who will lead me into that still more hidden and dimmer region where Thought weds Fact, where the mental operation of the mathematician and the physical action of the molecules are seen in their true relation? Does not the way to it pass through the very den of the metaphysician, strewed with the remains of former explorers, and abhorred by every man of science?"

This is a strangely modern cry to come from an early Victorian Yet it is a cry that was often to be heard in later years, and still is heard, chiefly from the mouths of those who do not understand the nature of scientific discovery For the "den of the metaphysician" is every scientist's study

The second problem arising from Maxwell's work, and to the solution of which he could contribute nothing, was the origin of the forces which one atom exerted on another How could one atom exert forces on another at some distance from it? Surely one of the arguments in favour of these atoms was that they explained the way in which forces, such as viscosity and pressure, could operate without the need to invoke action-at-a-distance? "It is in questionable scientific taste", he once said, "after using atoms so freely to get rid of forces acting at sensible distances, to make the whole function of the atoms an action at insensible distances"

Looking at this matter from the added experience of a later century, it is easy now to see that, at that particular stage, there was no conceivable chance that Maxwell should have solved this problem We have merely to recall that the very word 'electron' was only coined—by G Johnstone Stoney—in 1891, twelve years after Maxwell's death, and then it was nothing more than "a natural unit of electricity", with electrolysis as its basis A fairly well-developed theory of the isolated atom is an inescapable pre-requisite to any adequate account of the mutual interaction of two such atoms

But this leads to a third problem, in which Maxwell took considerable interest, and to which he frequently referred in his public lectures This is the apparently uniform and identical nature of every atom or molecule of a given kind Let us put this problem in his own words, taken from an address to the Mathematical and Physical Sections of the British Association

> "In fact one of the first conditions which a molecule must fulfil is, apparently, inconsistent with its being a single hard body We know from those spectroscopic researches which have thrown so much light on different branches of science, that a molecule can be set into a state of internal vibration, in which it gives off to the surrounding medium light of definite refrangibility—light, that is, of definite wavelength and definite period of vibration The fact that all the molecules (say, of hydrogen) which we can procure for our experiments, when agitated by heat or by the passage of an electric spark, vibrate precisely in the same periodic time, or, to speak more accurately, that their vibrations are composed of a system of simple vibrations having always the same periods, is a very remarkable fact"

In all this Maxwell was reacting to one of the new thought-forms of his age Darwin's *Origin of Species* was published in 1859, the year before Maxwell went to King's College, London In 1861 there had been the famous debate between Huxley and Bishop Wilberforce at the Oxford meeting of the British Association Scientific thinking had been deeply coloured by this new way of regarding Nature So Maxwell ponders on why the characteristic frequencies of emission and absorption of light do not themselves differ from one atom or molecule to another He returns to it again and again

> "Each molecule, therefore, throughout the universe, bears impressed on it the stamp of a metric system as distinctly as does the metre of the Archives, or the double royal cubit of the Temple of Karnac
>
> "No theory of evolution can be formed to account for the similarity of molecules, for evolution necessarily implies continuous change, and the molecule is incapable of growth or decay, of generation or destruction"

Again we can see that, with knowledge as it was at the time, this was bound to be an insoluble problem With our greater insight now, we can understand that without some form of quantum theory there could be no answers to questions about the identical nature of all atoms and molecules of the same substance Maxwell had got himself to the position where he was wanting to ask one of the most important questions physics ever has had to ask This is Why do we get quantization in certain phenomena, why are there quantum effects, showing discrete and not continuous variations ? This question lies at the very heart of modern physics, it dominates the whole of chemistry, and shows every sign of being no less important in biology But although Maxwell had indeed brought himself to the position where he would have liked to ask these questions, he could not do so Ideas of this kind were not 'in the air' at this time It was necessary to wait another forty years until Planck and Einstein had prepared the ground, only then could these questions be posed

We come to the fourth—and last—in this series of unanswered problems of Maxwell's day This concerns the formation of a molecule Atoms may —almost by definition—be unbreakable, but how did they ever get formed into molecules ? Surely no discussion that we can hope to bring forward will ever be able to pierce this mystery So he writes

> "The form and dimensions of the orbits of the planets, for instance, are not determined by any law of nature, but depend upon a particular collocation of matter The same is the case with respect to the size of the earth, from which the standard of what is called the metrical system has been derived But these astronomical and terrestrial magnitudes are far inferior in scientific importance to that most fundamental of all standards which forms the base of the molecular system Natural causes, as we know, are at work, which tend to modify, if they do not destroy, all the arrangements and dimensions of the earth and the whole solar system But though in the course of ages catastrophes have occurred and may yet occur in the heavens, though ancient systems may be dissolved and new systems are built, the foundation stones of the material universe remain unbroken and unworn They continue this day as they were created—perfect in number and measure and weight "

Those last two sentences are a wonderful illustration of pure Victorian prose Yet there is—for me—a certain irony in the fact that I read them the day before I saw the colour film of the first Eniwetok explosion of an atomic bomb For what I was witnessing in the disappearance of an island a mile or so in length was the simultaneous shattering of a very large number of these "unbreakable foundation stones"

Maxwell could not be blamed for not foreseeing this His distinguished contemporary, Prof Tait of Edinburgh, had written that "the great test of the reality of matter" was its "indestructibility" Molecules, and atoms, were to be regarded as part of the given world At that stage of inquiry it was pointless to be overmuch disturbed about their origin

(4) Recent Developments : Origin and Nature of Interatomic Forces

The time has come to look at the changes that have taken place since Maxwell's day It will be necessary to skate rather lightly over the arguments and the justifications for our present beliefs But perhaps this will not matter, since it is with the nature of these beliefs rather than the evidence for them that we are concerned

The four problems which were listed in section 3 can be summarized (1) What is a molecule, and its relation to its constituent atoms ? (2) What is the origin of intermolecular or interatomic forces ? And what is their law of dependence on distance and orientation ? (3) Why are molecules so invariable in character with no evolutionary or continuously varying properties ? (4) How does a molecule form ?

There is only one of these four problems in which Maxwell could have been expected to have made further progress than he did This is the form of the interatomic or intermolecular force and the progress would have been achieved by making more use of Clausius's virial theorem Clausius (1822–88) was nearly ten years older than Maxwell, and outlived him by nearly another ten years (Maxwell's dates were 1831–79) He is best known by his clear statement of the second law of thermodynamics, and his development of the concept of entropy But he had introduced the virial theorem, and so made possible an experimental estimation of the forces which led to the laws of imperfect gases In particular, if we suppose that the atoms of a gas, when at distance r apart, exert mutual forces on each other derivable from a potential energy $U(r)$, then the virial law leads to the virial expansion

$$pV = A + B/V + C/V^2 + \qquad (1)$$

where the successive coefficients A, B, C, are such that

$$A = nkT$$

(T = absolute temperature, n = number of atoms)

$$B = 2\pi nkT \int_0^\infty r^2(1 - e^{-U/kT})\,dr$$

Kammerlingh Onnes called these the first, second, virial coefficients B is due to collisions between pairs of particles, C is due to ternary collisions, etc Corrections are needed in the virial expansion (i) if the interacting species do not exert central forces on each other, and (ii) if the temperature is so low that quantum corrections are involved For the interaction of rare gas atoms at room temperatures neither of these is serious It follows that by a careful experimental determination of the constants in equation (1) it is possible to get information about $U(r)$. Since B is a function of U and of the temperature T, a complete knowledge of B as a function of T, more particularly if supplemented by some knowledge of C, should be sufficient to infer the form of $U(r)$. If Maxwell had been able to follow up this line of attack, the inadequacy of the hypothetical inverse-fifth power law would soon have been apparent.

As we said earlier, Maxwell could in principle have made progress along these lines. But he did not, and it was left until later before much real progress was achieved. This progress consisted in recognizing that the interaction $U(r)$ is best thought of as the combination of an attractive potential and a repulsive one. Van der Waals approximation to equation (1)

$$(p + a/V^2)(V - b) = nkT \qquad (2)$$

suggested that there were attractive forces (and the existence of surface tension confirmed this), and also that something similar to an atomic radius existed to show that one atom could not approach closer to another atom than a certain distance without overcoming considerable repulsive forces.

One part of the origin of these repulsive forces is easy to recognize. For if two atoms approach so close that the nucleus of one gets within the greater part of the charge-cloud of the other, the mutual interaction will be dominated by the ordinary classical Coulomb repulsion between the two positive nuclear charges. There is, however, another important contribution to this repulsive force, which will be described later. But it follows that at small distances the repulsive force is larger than the attractive one. This suggests an inverse power law of the form

$$U(r) = C_1/r^n - C_2/r^m \qquad (3)$$

where C_1, C_2, n and m are constants. The first term in equation (3) is the repulsive one, the second term is the attractive one, so that the repulsion at small distances requires that $n > m$. The most commonly adopted form of equation (3) is the particular case when $n = 12$, $m = 6$. This is the Lennard-Jones potential.

$$U(r) = C_1/r^{12} - C_2/r^6 \qquad (4)$$

A potential of this kind also fitted crystal dynamics, though the index n was not critical, and values in the range 9–15 could be chosen almost arbitrarily.

With such a potential it was possible to choose C_1 and C_2 so that the second virial coefficient was well represented. It could then be argued that, in this empirical fashion, the effective law of force had been determined. All this could in principle have been accessible to Maxwell.

However, an empirical knowledge of $U(r)$ is not sufficient by itself. We want to know more about the origin of these attractive and repulsive forces, and we want to be able to calculate them—in any event sufficiently accurately as to feel confident that we are giving the correct explanation of their origin. There is also a further point closely related to the first and last of the four problems listed earlier. Why is it that some pairs of atoms interact with a potential energy of the general type of equation (4), and other pairs of atoms actually join together to form stable molecules? The subject of interatomic forces is thus linked with the subject of valence. In this field Maxwell was under the disadvantage that official chemists were only just beginning to establish any serious theory of valence. The old electrostatic picture of Berzelius, in which the molecule HF would be treated as if it were H^+F^-, was manifestly unable to account for covalent bonding, as in H–H or F–F. In fact, it was only in 1861 that Kekulé was talking of fixed atomic valences, and the traditional symbol for a chemical bond, the familiar horizontal line as in H–H, was being introduced by Odling, Crum Brown, Frankland, Couper and others. It soon became quite clear that there must be some entirely additional factor to be considered, not included in equation (4): this factor would enable us to decide whether two or more atoms would or would not form a molecule, and whether two molecules would join to form a larger molecule, or (more commonly) interact according to some such law as equation (4).

There are thus three issues to settle. (1) What is the origin of the attractive term in equation (4) and why is it an inverse sixth-power potential? (2) What is the origin of the repulsive term in equation (4)? (3) Why is there sometimes an attractive force instead of the repulsive term, and this attractive term is sufficient to lead to the formation of a stable molecule? We must consider these in turn.

(5) Long-range Dispersion Forces

If two atoms or molecules carry net charges there will be quite straightforward forces of attraction or repulsion due to conventional Coulomb (that is, inverse-square law) forces between these charges. We neglect this possibility, since it is unusual and trivial. We have to show, instead, why two neutral atoms or molecules exert long-range attractive forces on each other.

Consider first two hydrogen atoms, as in Fig. 1,

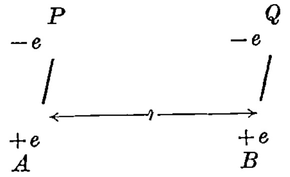

Fig. 1

the nuclei of which A, B are a distance r apart. Each atom has one negative electron (at P and Q respectively). The combination of $+e$ at A and $-e$ at P is nearly equivalent to an electric dipole of magnitude $e \times AP$. Similarly, the combination of $+e$ at B and $-e$ at Q is nearly equivalent to an electric dipole of magnitude $e \times BQ$. These two dipoles will exert forces on each other. For the mutual potential energy of two dipoles $\mathbf{m}$ and $\mathbf{m}'$, separated by a distance $\mathbf{r}$, is

$$\frac{\mathbf{m} \cdot \mathbf{m}'}{r^3} - 3\,\frac{(\mathbf{m} \cdot \mathbf{r})(\mathbf{m}' \cdot \mathbf{r})}{r^5} \qquad (5)$$

It is obvious that this varies with distance according to the law r^{-3}. Now the electrons are moving, so that we must take some sort of average of this potential. In wave-mechanical language, we treat the expression in equation (5) as a perturbation acting on the two atoms The first-order energy change is zero, and so we need to go to second order As a result the change in energy is of dimension $\left(\frac{1}{r^3}\right)^2$, that is, r^{-6} Following London, who first set out this analysis, we call this the dipole–dipole interaction There are, naturally enough, dipole–quadrupole, quadrupole–quadrupole interactions, for which the energy varies, with a higher power of $1/r$ When the atoms or molecules have more than one electron each, the instantaneous dipole moments in equation (5) are obtained by summation of the separate one-electron terms

In this way we can see the origin of the attractive term C_2/r^6 in equation (4) But in addition the analysis shows that the coefficient C_2 is proportional to the product of the polarizabilities of the two interacting systems In favourable cases the precise value of C_2 can be determined by purely theoretical means We describe these forces as dispersion forces because by far the greater part of the energy comes from the outer and most loosely bound electrons these are the same as the electrons responsible for the dispersion of light

There are two other contributions to these long-range attractive forces both are dependent on the existence of a permanent dipole moment in the interacting systems If one molecule has a permanent dipole moment, this will interact with the permanent moment of the other It will also polarize the other Both these phenomena lead to a net force of attraction In both cases the associated energy varies as r^{-6} Thus the constant C_2 in equation (4) represents the sum of three separate contributions All three are often of the same order of magnitude, with the induction force tending to be the smallest

More recently, it has been shown (first by Casimir and Polder) that on account of the finite speed with which the electromagnetic field is transmitted from one molecule to another, the dispersion energy varies as r^{-7} rather than r^{-6}, when r is large Fortunately, this result, however amusing, is scarcely of any experimental significance

(6) Overlap Repulsive Forces

To understand the repulsive forces in equations (4) and to be able to decide in what cases this repulsive force should be replaced by a very powerful attractive force, leading to the formation of a stable molecule, we need the wave mechanics of Schrodinger, and the exclusion principle of Pauli A simplified account of these, as they affect an isolated atom, can be given as follows

Each electron in an atom must no longer be described in terms of some sort of planetary orbit around the nucleus, but in terms of a charge-cloud These charge-clouds, or atomic orbitals as they are usually called, have size, shape and energy If we build up an atom by first removing all the electrons and then feeding them back to the nucleus, one at a time, we shall presumably begin by first filling the lowest energy levels The Pauli principle tells us that each allowed orbital will only accommodate two electrons, and then they must have opposed spins This means that the second pair of electrons will have to go into a higher energy orbital, and this process continues until all our electrons have been accounted for One important result of this is that the last few electrons to be added to the atom have much higher energies than the first few, also, they are forced away from the first ones, and take up places farther out from the nucleus It is thus that the periodic shell structure of a heavy atom is explained We could almost summarize by saying that Nature is so designed that we cannot have too many electrons in the same region of space without having to pay for it in terms of higher energies (This is the wave-mechanical analogue of the semi-classical theorem that in any volume h^n of phase space, where n is the number of spacial co-ordinates, there is just one allowed energy level)

Now let us see what happens if we bring two helium atoms together from a large distance Each separate helium atom has two electrons, which complete its inner shell (the K-shell) and so lead to the familiar inert gas structure In Fig 2a are shown the two atoms a long way apart, and the spheres within which each separate charge-cloud is effectively confined We have to say 'effectively confined' because strictly the density of the charge-cloud extends to infinity However, on account of its exponential decay with distance we can draw boundary surfaces such as those of Fig 2a, such that a large fraction, for example 95 per cent, of the charge lies within those surfaces It is in this way that we define the size (or Van der Waals radius) of an atom, a matter about which, of course, Maxwell was powerless to say anything really fundamental These two pairs of electrons so successfully 'occupy' the volumes shown in Fig 2a that no other electrons can get within this volume without raising the energy

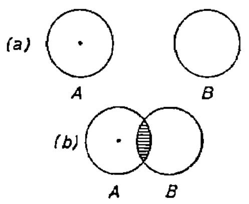

Fig 2 (a) Two atoms A and B well separated from each other (b) The same two atoms brought so close that their charge-clouds overlap The overlap region is shown shaded

Next consider what happens when the two atoms are brought closer together After a while their boundary surfaces overlap, as indicated in Fig 2b But this causes trouble, since in the shaded volume, which is common to both atoms, there are now too many electrons In a rough sort of way we can say that some of them must go into (locally) higher energy states This means that when the atoms get within each other's boundary, the energy rises The prime cause of this rise is the Pauli principle But, of course, a rise in energy of this kind is entirely equivalent to a repulsive force Thus, the origin of the repulsive force (equation 4) is essentially the influence of the exclusion principle, operating as soon as the separate atomic charge-clouds overlap We may therefore call these repulsive overlap forces

A similar argument will apply whenever we bring together atoms or molecules with completed electronic shells, since, when the two boundary surfaces overlap, the Pauli principle will begin to operate, just as in the case of two helium atoms just described Furthermore, it appears that the energy rises very rapidly as the overlap increases The Lennard–Jones formula (equation 4) represents this by the term C_1/r^{12}, which increases rapidly as r decreases Accurate calculations by Bleick and Mayer for helium and neon, using wave-mechanical methods, suggest that a better form may be an exponential one, so that instead of equation (4) we should write

$$U(r) = C_1e^{-ar} - C_2r^{-6} \qquad (6)$$

Fortunately, however, there is little real difference in predicted behaviour when we use the 6–12 formula (equation 4), or the exp-6 formula (equation 6)

(7) Valence Forces

The third problem enunciated at the end of section 4 was concerned with the fact that sometimes, instead of a repulsive force as described in section 6, we find a strong attractive one This is, of course, nothing other than what the chemist calls a valence force

To understand these valence forces let us suppose that in Fig 2a we were bringing together two hydrogen atoms instead of two helium atoms The essential difference is now that each atom has only one valence electron rather than two Each boundary sphere can therefore hold one further electron without the operation of the Pauli principle necessarily involving large repulsive energies The two atoms may therefore approach closer together, as in Fig. 2b, so that their boundary surfaces overlap But this is only possible on one condition—that the spins of the two electrons are opposed (that is, antiparallel) If the spins are parallel, there is anti-bonding with a large repulsion, if the spins are opposed, there is bonding Thus the role of the spin is now quite crucial

We still need to show that, when the two spins are opposed, there is bonding What we have so far shown only amounts to a proof that there is no overlap repulsion. The simplest way to see this is by means of the diagram in Fig 3. Let us consider just one electron in the presence of two separate attracting nuclei A and B If we are going to apply this argument to the hydrogen molecule the nuclear charges will be $+e$, and the electron at P will experience a potential energy $-e^2\left(\frac{1}{r_a} + \frac{1}{r_b}\right)$. Let us now compare the values of this potential energy when P moves on the sphere around A, represented by the dotted circle The potential energy is lowest (largest negative value) when P is at Q, on the axis of the molecule, between A and B, and it is highest when P is at R This means that the electron will tend to concentrate itself around Q rather than around R Alternatively, we may say that the charge-cloud will build up a greater density around Q, drawing charge from the outer regions of the molecule towards the centre of the molecule, as represented schematically in Fig 4 Now the negative charge at Q will serve to pull both nuclei A and B towards it In this way there is a force of attraction If it is sufficiently strong, it will lead to the formation of a stable molecule.

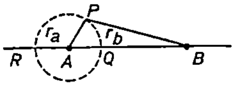

Fig 3

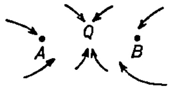

Fig 4

It may now be objected that in H_2 there are two electrons This modifies the argument, but without altering the result For both electrons will tend to concentrate their charge-clouds around Q However, the mutual Coulomb repulsion between these electrons will cause them to 'elbow' each other away from Q But some excess charge will still remain around Q, leading to the same result as before In a strict calculation we should have to calculate this distortion of the original charge-clouds, and we should also need to take account of the kinetic energy of the electrons Here, too great a concentration operates to produce an effective repulsion For by concentrating an electron in a small region (for example, a rectangular or spherical box), we reduce the wavelength λ of the associated de Broglie waves Now the momentum p is related to λ by the de Broglie formula $p = h/\lambda$ So a decrease in λ implies an increase in p, and therefore in the kinetic energy $p^2/2m_1(p^2/2m = \frac{1}{2}mv^2)$. Fortunately, however, this increase in kinetic energy is less than the decrease in potential energy The argument for this assertion follows from the virial theorem previously discussed, where it can be proved that in the equilibrium configuration the kinetic energy gain relative to the two isolated atoms is only one-half of the corresponding decrease in potential energy So, in an almost totally unexpected way, the same theorem which Maxwell could have used to obtain empirical information about interatomic forces in a gas can now be used to deal with situations such as are involved in chemical bonding, of a type that Maxwell could not conceivably have discussed

(8) Conclusion

We can now see how impossible it was that Maxwell should have been able to describe either the dispersion attractive forces, or the spin repulsion and attractions For, implicit in the account of sections 5–7 there lies the discovery of the electron by J J Thomson, the nuclear atom of Rutherford and Bohr, the idea of electron shells associated with Moseley, the concept of stationary states with no radiation (how appalled Maxwell would have been at the almost cavalier way in which his superb development of the equations of the electromagnetic field had to be abandoned at the microscopic level !), the wave equation with its quantum conditions, and the Pauli exclusion principle These concepts, which are the peculiar glory of modern physics, have changed our way of thinking about interatomic forces so utterly that, although the problems are the same, the accounts given in the first and second parts of this account appear to have almost nothing in common Indeed, there are those who, when hearing of wave equations, wave functions, charge-clouds and their overlapping, or spins and their pairing, and realizing that not one of this whole catalogue has the objective character which will permit us to hold it in our hand and look at it, will want to recall some of the words of Maxwell which I quoted earlier If Maxwell himself had been here to-day, he might have said "Did you read that sentence of mine about passing through the metaphysician's den ?" We should have had to reply "This way may, in truth, be strewed with the remains of former explorers, but it is only because they have passed along it that we can complete the story which you began to tell".

THE EARLY DAYS OF CHEMICAL FERTILIZERS

By G E. FUSSELL

BEFORE the third decade of the nineteenth century farmers used nothing that could properly be called a chemical fertilizer The just reason for this was that none was available Most of the fertilizing agents applied to the soil were organic—farmyard manure, the sheep fold, waste products of the house, animal and plant refuse, wool and hair waste, shreds of leather, tanner's bark, and organic wastes from soap and sugar boiling In addition to these the farmers used the so-called fossil manures, lime, slaked and unslaked, chalk, marl, sea shells, and mixed their soils as they deemed it necessary and rewarding They sanded the clay and clayed the sand and the fen All this was traditional, and most of it had been used for centuries, if not millenia

These materials were used empirically according to the lessons of experience derived from practice No farmer would, I suppose, have claimed to understand the chemical processes which occurred as a result of his action indeed, the chemists themselves had been contented with speculation until the seventeenth and eighteenth centuries when the new experimental work so widely extended our knowledge of the world around us, and provided a groundwork of the science of plant nutrition

The early philosophers who devoted themselves to plant chemistry were handicapped by their acceptance of the traditional four elements of classical times, and the three principles of Arabic thinking but several thought that nitre or saltpetre was the prime promoter of vegetation Francis Bacon, writing in 1627 [1], postulated "it is true, as I conceive, that such Earth as hath Salt-Peter bred in it, if you can procure it without too much charge, doth excel" Evelyn repeated this more emphatically in 1675. If saltpetre was plentiful and cheap, "we should need but few other composts to meliorate our ground", and Sir Kenelm Digby actually made an experiment by watering barley plants with a weak solution of nitre in 1675 "to their great benefit"[2] Other distinguished chemists of a later date expressed something of the same opinion; but their ideas could not be put to the rough test of practical trial because supplies of the material were unobtainable The quantities to be obtained were wanted by the 'armament industry' for making gunpowder

In the seventeenth century, J R Glauber, whose name is immortalized in Glauber's salts, obtained saltpetre from the floors of cattle sheds, then one of the main sources of supply He argued that it derived from the droppings and urine—the floors were only earth in those days Consequently, it must have been a component of the feed, which was, of course, plants He made some trials of saltpetre as a fertilizer, and obtained higher than average yields He concluded that saltpetre was "the essential principle of vegetation", and argued that the effect of all manures commonly used was the result of the saltpetre they contained[3]

If any farmers ever heard of Kenelm Digby's or Glauber's experiments, which seems to be extremely unlikely, they could not have profited by them, because they could not have purchased the material Only about one hundred and fifty years later did sufficient supplies come on the market—by way of importation from the East Indies A firm, Forman and Hadow, of 51, Lime Street, London, sold the material Hadow had a house at Colney, Herts, where he used it as a fertilizer between 1824 and 1828 He may have done so before because some farmers in the county had already been using it for some years What, apart from the fact that they could get it, caused these men to begin using it is now impossible to discover Probably some of the older among them had attended Humphrey Davy's lectures on agricultural chemistry given to the Board of Agriculture between 1802 and 1812 He had said that saltpetre or nitre might possibly furnish azote (nitrogen) to form albumen in plants, and that it should therefore be useful for wheat The fact, however, as was said at the time, seems at variance with the theory Davy thought that the nitrous salts were too valuable for other purposes to be used as manure[4]

Some farmers in the neighbourhood of Hitchin evidently did not agree with him because several of them were using it in 1828, and one or two had been doing so for a fairly long time For example, T Wilshire had used it for about twelve years on his heavy clay soil He applied one hundredweight per acre, and made comparisons with dressings of salt and soot His observations on the results are lost to us, but he found the saltpetre effective on cereals and grass, not on roots

John Lee of Ippolits had used this fertilizer even longer He spread 1–2½ hundredweights per acre He found the result was to stimulate a large bulk of straw, but he did not think white wheat yielded so well The saltpetre caused mildew, or so he imagined He preferred soot as a top dressing for wheat, and he certainly had a fair experience to guide him. He had found that if barley was dressed with saltpetre the following crop of clover and grass did well

J Curling of Offley Hales was more in favour of saltpetre He thought it good on all soils, and for both cereals and grass It increased the straw, which was anything but a nuisance then, and the yield was far superior to that produced by any other manure Unfortunately, neither of these men gives any actual figures, and there is no measure to judge the exactitude of their impressions Curling sowed the saltpetre well after the crop was up, but before doing so he mixed it "carefully and intimately" with ash in the proportion of 1¼ hundredweight to a small cartload (rather a vague measure) of ash One wagon load of 3 tons of saltpetre dressed 50 acres whereas an equal quantity of soot would only do 4 or 5 acres There was a saving of at least 15 shillings an acre

Other farmers who used saltpetre were Mr Sharpe bailiff to E H Delme Radcliffe, Esq , H Crabbe of Temple Dinsley, Mr Crawley (no address given), Mr Oakley of Preston and John Cook of Hillend The last-named was a cautious man, and went to the

East India Dock direct for his supplies, which were tested at Apothecaries Hall The inferior sort proved to be mixed with common salt Mr Roberts, steward to W Hale, Esq , and Mr Lucas of Hitchin also used it Lord Dacre had done so, and found it encouraging The last would, William Hawkins thought, "be peculiarly important in the eyes of those who might have hesitated making experiments on the credit of gentlemen whose names were unknown to them"[5] It is not impossible that a conversation between Lord Dacre and Lawes led the latter to produce chemically his superphosphate of lime

The news of this practice and these experiments must have been pretty well spread abroad The notion reached, what was then far-away, Scotland Thomas Bruce of Grangemuir, who was acquainted with Forman and Hadow, learned all about it, and was so much impressed that he imported some saltpetre from London He used it on wheat sown after potatoes, and the results were so good that he tried to persuade the Highland and Agricultural Society to institute some definitive experiments[6]

Those farmers who tried saltpetre are to be commended for their initiative, but their efforts were brought to nought by the importation of the first cargoes of Chilean nitrate of soda late in the 1830's Lord Dacre, who had tried saltpetre on the grass in his park at The Hoo, near Welwyn, for two or three years about 1820, found that it produced a heavy crop at the expense of the finer herbage For a while he gave it up, but then tried it again and changed his opinion of its worth In 1839 he tried some of the newly imported nitrate of soda, applying an equal money cost of each to an equal area—quite an unusual way of conducting an experiment The nitrate was about 30 per cent cheaper than saltpetre The first was sold by William Mitchell, Commercial Sale Rooms, Mincing Lane, at 19*s* 6*d* per hundredweight, whereas saltpetre (nitrate of potash) cost 25*s* duty paid Another advantage of the nitrate of soda was that it rarely contained more than 5 per cent of 'alloy' while saltpetre was impure to the extent of 30–50 per cent Mitchell had sold nearly 2,000 tons of nitrate of soda in the previous year, and had a stock of less than 1,000 tons at the docks Of saltpetre he was carrying between 4,000 and 5,000 tons, but considered that a demand for 1,500–2,000 tons for agricultural use would raise the price too high for it to be economic for that purpose[7]

Other farmers became interested James Everitt of North Creake, near Fakenham, Norfolk, was one He used saltpetre in 1838 as a top dressing on growing crops, which was usual, at 1 hundredweight per acre This was on an experimental plot of two 'rigs' each 1¼ acres The increase over the untreated land was at the rate of 6½ bushels an acre plus one-sixth more straw In 1839 he estimated the increased yield on treated plots at 4 bushels wheat and 15 bushels oats plus 11 hundredweight straw above average Nevertheless, he was so impressed by the opinion of an eminent professor of agriculture that American nitrate of soda was "better calculated for agricultural purposes" that he bought 5 tons for use in 1840 [8]

Saltpetre remained the interest of a select few farmers only, and one of them, George Kimberley of Trotsworth, Surrey, thought the history of the material was that of all artificial manures, especially the saline, which, successively and hastily adopted after a few fortunate experiments "have started it into a fashion" It had been used since the Hertfordshire experiments, but only by the enthusiastic minority, not as a standard auxiliary manure Kimberley had himself become sufficiently interested to try the material for a couple of years in 1826 and 1827, using a plot isolated in the middle of a seeds crop, which had received the usual dressing of ten good cartloads of dung per acre The untreated piece was weak and poor in the spring compared with a thick, rank growth on the dunged area, but fourteen days after the trial plot had been treated with saltpetre it looked very much better than the other There was no difference in the succeeding wheat crop, but the cost was £5 12*s* an acre for the horse manure including spreading, while that of saltpetre was only £2 15*s* 6*d*

Kimberley had formed no theory about it, practical facts were, in his opinion, of more service and better understood On the basis of these and other experiments he recommended the substance, finely pulverized, as a top dressing on all crops, at the rate of 1–1¼ hundredweight per acre on the first spring growth He remarked that Cuthbert Johnson, a respected farming writer of the time, thought its agricultural use had not been examined so carefully as it ought to have been It is probable that the scanty supplies to be had were a sufficient reason for this neglect In 1834 the anonymous author of *British Husbandry* declared that it was rarely used as a manure for that reason He only mentioned it as a matter of secondary interest to a few speculative farmers For the rest he quoted Davy and the Hertfordshire experiments[9] Subsequent writers of text-books displayed an equal lack of enthusiasm All that John Donaldson could find to say was that "of late years nitre has attracted some notice as a manure" As a top dressing on wheat it had exceeded the value of rock salt, but not invariably On hay grounds it had promoted one-third more produce its effect on chalk grounds was generally good J W F Johnston could only say that besides being made into gunpowder it had "also been recommended and frequently and successfully tried by the practical husbandman, as an influential agent in promoting vegetation"[10]

Only a small minority of farmers tried saltpetre Even if those recorded is multiplied by five or ten to include those whose efforts did not see print the number would still be an insignificant proportion of the total Many more tried nitrate of soda Not only was it cheaper but also more of it reached the market, although some of the quantity imported was used for chemical manufacture The speculative or advanced farmers who bought it were more widely scattered over the country, too

In May 1839, the Earl of Zetland had no less than 1 ton sent to Upleatham, Yorkshire, and used it at 1¼ hundredweight per acre on wheat, turnips and meadow land Nothing came of it on the turnips, it was applied too late on the wheat The results on grass were astonishing A treated plot of 90 square yards produced 30 stone (14 lb) of hay the same area untreated only 14 stone There was a great increase of aftergrass, too, which the cattle and sheep ate greedily Of course, this was only one year's results what later consequences would be it was impossible to say[11] Sir George Legard, another Yorkshire landowner, found the results of his trials were inconclusive He made comparisons between nitrate of soda on one acre of 40 acres of wheat after clover ley on wold land, eaten off by sheep Rape dust at 8 bushels an acre was sown the nitrate at 1 hundredweight The acre treated gave a larger bulk of straw than the rest, but the grain was lighter In a comparison with soot, the sooted wheat was better Against bones on turnips nothing the results were quite inconclusive Angus of Neswick, near Driffield, was more ambitious, and made comparative trials with various manures, but did not include nitrate of soda[12]

David Barclay of Eastwick Park, near Leatherhead, Surrey, was a prophet, or, rather, a far-seeing man Though he made trials of nitrate of soda and recorded others, he felt that the investigations of the effects of its use were likely to advance science rather than practical farming, a division of function that the Royal Agricultural Society's motto had joined together Manure was, he said, loosely classed as real or nutritious manure, that is, dung, and stimulating manure, that is, lime or other mineral substances exciting other substances to make plant food The German writers now say, he went on, that dung acts by reason of its chemical elements, some of the minerals that constitute the food of plants This was, of course, the theory advanced more particularly by Liebig, but suggested before him by Sprengel and Schubler Barclay went on to the argument from the results of applying urine, soot and gas liquor, all of which contain ammonia Nitrate of soda, he said, made it possible to go a step further Ammonia is a combination of nitrogen with hydrogen Either of these might be the source of its power over vegetation "but we have seen that saltpetre or nitrate of potash and cubic saltpetre or nitrate of soda, act on crops in the same peculiar manner as fermented urine, soot or gas liquor, which do not contain hydrogen but do contain nitrogen in the form of nitric acid Nitrogen therefore appears to be the active principle in all five substances Liebig in proving the efficacy of ammonia has shown the necessity of nitrogen in forming gluten" This he condemned as only guesswork, and demanded scientific research into the action of manure and the food of plants "We should all", he said, "try nitrate of soda"

Many farmers were already doing so, not to speak of Barclay himself His own experiments led to very different results on different crops The standard of judgment was severely practical Not only were the comparative yields studied—though I gather the comparison was on the basis of accepted averages rather than control plots—but the financial result, that most important factor, was taken into account Barclay, too, collected all the accounts he could of other people's trials Several of these were Surrey farmers Walter Calvert of Ockley Court, George Dewdney of Castle Mill, Drewitt and Sons of Piccard Farm, Guildford, these last well known in Government circles having given evidence to at least two Select Committees Besides these there were John Burgess, Elmhurst, Great Missenden, Bucks, John Raymond Barker, Fairford Park, Glos , John Grey of Dilston, Northumberland, W H Wilson, Didlington Hall, Brandon, Suffolk, William Greaves, Bakewell, Derbyshire, John Muskett, Fornham, Suffolk, W H Hyett, Painswick, Glos , Joshua Rodwell, Alderton, Woodbridge, Charles Newman, Court Farm, Hayes, Middlesex

It would be tedious here to recite all the results these people noted Suffice it to say that Barclay found it impossible to reconcile the different results given by his various correspondents, an experience which, had he known it, is not unusual in the initial stages of a co-operative trial of new material Disappointedly he felt that these conflicting records were calculated to discourage the use of it as manure "The experiments which have been made with this new manure", he said, "require to be repeated and their accuracy established before any practical conclusions can with certainty be built upon them", a statement the justice of which few would deny He thought that judiciously applied it would prove a most valuable manure, and had decided to carry out further trials on a larger scale[13]

Other people continued to carry out comparative trials as between saltpetre and nitrate of soda, but the price and adulteration of the first made "it a poor competitor", and by the end of the 1840's few persons would have thought of using it Some of the men who made trials included the so-called Peruvian guano, salt, nitrate of potash, various types of manufactured guano put out by fertilizer firms, and the usual organic manures Lime was also used, and such things as rape dust Among them were such eminent men as John Grey of Dilston and John Hannam, who won a prize of £50 from the Highland and Agricultural Society[14] As might have been expected nothing conclusive could be determined from this hotch-potch of uncorrelated field trials, not carried out to a standard pattern under one supervision Some optimism was rightly expressed, and the general opinion formed that nitrate of soda was a useful top dressing for a variety of crops in a variety of conditions, but some of the most careful observers among those who used the materials remarked sadly that the results were not always the same This did not prevent the use of nitrate of soda, for example, in increasing quantities

But what aroused most interest was the treatment of bones with sulphuric acid to make superphosphate of lime The use of bone waste had been written about from the 1770's because some observers had not then been acquainted with its use in the neighbourhood of Sheffield, where it was the refuse from the manufacture of knife handles and such things

Fifty years later the use of bones had become popular in several parts of the country For example, they were used on the dairy pastures of Cheshire to replace the phosphates lost through the dairy industry The demand was so large that "the import value rose from £14,395 in 1823 to £254,600 in 1837"[15] They came in mainly through the port of Hull, where they were ground down into the sizes preferred by the farmer During the twenty years prior to 1834 the farmers on the calcareous soils of Lincoln and Yorkshire had generally adopted bones as a dressing for turnips The best results were said to be obtained when this material was mixed with vegetable or coal ash The growth of the young plant stimulated and thus escaped the ravages of the 'fly' Long before this time, but probably no more than half a century or so, some people had used them after burning the bones into ash, when they had the same effect as sulphate of lime or gypsum, but the effect was not then considered so good as uncalcined bones If placed at the bottom of the farmyard, that is, where the cattle fed, the urine might be expected to decompose the bones, or they could be partially broken with a hammer Some farmers had installed their own grinding machines Similarly it was said that bones, after being broken and boiled for grease, were sold to the farmers near London It was agreed that the smaller they were ground the better The application of 120 bushels per acre of small bones was estimated to be equal to 40–50 cartloads of 'fold' manure, that is, that produced by wintering cattle in yards or covered sheds

In Warwickshire the farmers had formerly bought about 5,000 bushels of horn shavings, waste from the comb and horn lanthorn industry at Kenilworth, but had largely forsaken this by 1830 in favour of bones[16] The farmers, who used bones by themselves or in conjunction with other material as compost or decomposed as suggested here, recognized that their value lay in their content of phosphate of lime This took some time to become available as plant food in the soil, the second crop often getting more benefit than the first

Among chemists it had long been generally known that soluble phosphate of lime was produced by adding sulphuric acid to bone ash Berzelius, the great German chemist, made a careful study of this and other phosphates[17], but it was Justus von Liebig, in a paper read to the British Association for the Advancement of Science in 1840, who pointed out the value of this preparation, made by adding sulphuric acid plus three or four parts of water at the rate of half the weight of finely crushed bones After allowing the mixture to digest for some time 100 parts of water was added, and the whole spread as a liquid manure, or, at least, that was the treatment that Liebig's experiments had indicated The question of priority of discovery, if such it could be called, has long been argued Lawes had made some pot experiments in 1839, used the material on half an acre of turnips in 1840, and on a much larger area in the following year[18] He took out a patent for the manufacture of superphosphate of lime in 1842

The taste for comparative experiment must have been stimulated by the novel accessibility of the new manures, Chilean nitrate, Peruvian guano, ground bones, as well as by the efforts of the new Royal Agricultural Society, which were supplementary to, and possibly productive of more enthusiasm than, those of the societies, great and small, formed in the eighteenth century Something, too, must be attributed to the expansion of chemical knowledge that promised the possibility of gaining more definite information about the value of the different substances It is perhaps significant that farmers in the most improved parts of the country were those who carried out the experiments

John Marshall of Riseholme, near Lincoln, made a trial of six different systems of manuring in 1841, whale oil, bones, night soil and crushed oyster shells with and without burnt ash, and one plot with burnt ash only Marshall planned this experiment well, but, of course, could not base final conclusions on one year's work He did, however, decide to reduce his consumption of bones from 2,000 bushels to 200, and by substituting other manure hoped to save £175 His personal preference was for night soil compost dried sufficiently so that it could be drilled[19]

But after Liebig's paper and Lawes's patent dissolved bones impinged most strongly on the agricultural imagination Lawes himself abandoned the use of bones as a base, and substituted other forms of phosphate in his factory Members of the Morayshire Farmers Club carried out trials of this material, prepared, I gather, on their farms, and the Club issued a report Comparison was made between bones and guano, bone dust and bone watered with sulphuric acid Bones alone, dung and bone dust were applied as a contrast The Duke of Richmond ordered an experiment to be made, and found the treated bones gave the best results Philip Pusey, in his comments on these trials, referred to Sprengel and Hannam, and declared the results "wonderfully according to the predictions of chemical science, but not yet (in 1843) completely established"[20] That this was so is demonstrated by the fact that farmers went on making comparative trials, and publishing their results[21]

John Hannam, who became something of an authority on fertilizers at this time, not only made trials but also discussed theory He was somewhat doubtful of the conclusions drawn from Sprengel's experiments that only the inorganic part of the bones was the fertilizing agent The opposite opinion was held by Prof Johnston Hannam made the best of both worlds by asserting that both might be considered fertilizers In his opinion burnt bones acted more rapidly than fresh, and fresh when reduced to fine powder "Burnt bones absorb a large quantity of water by means of which the organic acids in the soil more easily act upon the phosphates", and rendered them soluble Oddly enough, Hannam knew of Lawes's experiments, but had not made himself acquainted with them[22]

When Lawes decided to abandon bones and to seek other sources of phosphate, he imported some Spanish phosphorite from Estremadura, and made trials with it Prof Charles Daubeny, who had visited Spain in this connexion, tried it at the Botanic Garden, Oxford, and concluded that since Spanish phosphorite was wholly destitute of organic matter, the benefit derived from its use came from the phosphate of lime Harry Verney made trials in Buckinghamshire, as did a couple of farmers in Hereford[23]

By this time, brief though it was, Philip Pusey was able to say that Dr Liebig's great discovery of dissolved bones in sulphuric acid for manure had been clearly established by the experiments of the Duke of Richmond and others Nothing was wanting in 1846 but a plan for bringing it into the ordinary routine of farming, a necessity which was met by the establishment of Lawes's factory for the manufacture of superphosphate of lime Indeed, Lawes had a measure of priority over Liebig in the discovery of the process, as well as successful sales of his product, whereas Liebig's patent manure failed to meet expectations for reasons, that have only been understood more recently

The early days of chemical fertilizers may be considered to have ended by 1850 Supplies of Chilean nitrate and Lawes's superphosphate were by then to be had in generous quantities, and sulphate of ammonia was derived from what was known as gas liquor, a waste product of the expanding gas-light industry

By that date (1850) the effect of the use of these fertilizers was already noticeable in the increased yields per acre on British farms, and perhaps in other European countries, although farmers on the Continent began to use them at a slighter later date than those in Great Britain For example, the yield of wheat in England had risen from about 20–22 bushels an acre in the late eighteenth century to about 26 bushels in 1850 [25] Comparable increases had probably occurred in the yield of other cereal crops, but the yields in the eighteenth century have not so far been fully established With the continued and expanding production and use of chemical fertilizers during the second half of the nineteenth century the yield rose to about 32 bushels an acre and has become rather more at the present day Similar increments in the acreage yield have been obtained both in wheat and other crops in Britain, the Continent, and the great grain-producing countries of America and Australasia.

It cannot, of course, be claimed that all this increase has been due to the effect of the use of chemical manures only Science has performed other functions in breeding new and more productive varieties, and has made great advances in the control of plant pests and diseases, all of which have helped the farmers of the world to produce more and more adequate supplies of food for society, though the whole world is not yet free from hunger Some of the credit for this great advance, too, must be given to the engineers who have provided the modern power units and the machinery used with them as well as means of moisture conservation and disposal So many factors are involved that it is difficult to make a real assessment of the effect of each, but the chemical fertilizers the use of which was directed by science, which is also guiding their production, certainly played a major part in the early days of the nineteenth century, and have continued to be most important, indeed increasingly important, to the present day

OBITUARY

Dr. H. Hamshaw Thomas, M.B.E , F.R S

HUGH HAMSHAW THOMAS, who died on June 30 at the age of seventy-seven, was the senior British palæobotanist He spent his whole working life in Cambridge apart from the two World Wars In the First he served with the Royal Air Force in the Near East, and in the Second was in charge of a team of Air Force Intelligence men near Henley-on-Thames

His first important palæobotanical papers published in 1909 and 1911 were careful studies of petrified Calamite leaves and in the well-established tradition of Scott, and gave no sign of what was to come However, Seward suggested that he should re-investigate the British Jurassic plants—and it must then have seemed a simple and short task At that time an ordinary fossil plant, 'impression with carbon', as it was called, was just a black mark on a rock and observation with a hand lens was the limit However, Nathorst in Stockholm was developing the intelligent study of fossil cuticles, and Thomas went there to fit himself for advanced work He came away with a robust view at the opposite extreme such a fossil was no mere black mark but a whole organ, albeit compressed, and failure to see every cell of its structure is failure of technique or observation.

Thomas was also inspired by Robert Kidston with whom he collected in the Scottish coalfields From him he learnt that the tradition that the proper subject for a palæobotanist's studies is the specimens provided by a geologist or by an early amateur collector is no good He must collect for himself, study his material and then go back and get more; he ought not to publish until he has a great collection confirming every point repeatedly

These perfectionist ideas dominated Thomas's work, but they had their perils, for like Kidston, Thomas only described a fraction of the good things he discovered However, they combined happily in his famous paper published in 1925 on the Caytoniales, those tantalizingly Angiosperm-like plants This family is Thomas's creation, for although small pieces were known as isolated and uncommon fossils they were hopelessly misunderstood Thomas gathered together hundreds of specimens over the years and patiently attempted to section them His success was only moderate, for he could see the more robust cells in about a tenth of the specimens he treated, but it was much the best work of its kind that had been done A good many shook their heads over Thomas's synthesis of *Caytonia* but later work has confirmed it

The first important fruit of his work with Nathorst was a paper (in 1913 with Dr N Bancroft) on the cuticles of "Fossil Cycad" leaves, that welter of confused genera and species They showed that the cuticles divided them sharply into two groups, the Bennettitales and the Nilssoniales or true cycads Others working over the same material have merely sharpened the distinction which remains the beginning of orderly treatment

Thomas's last major paper in palæobotany was on the Corystospermaceae (1933), another entirely new family of Mesozoic Gymnosperms, this time from South Africa, where he spent a good deal of time with his wife These are perhaps more important than the Caytoniales, for they are by no means rare, but apparently dominant over the southern hemisphere throughout the earlier Mesozoic His election to the Royal Society happened in the next year Apart from these contributions, which opened entirely new fields, he wrote a good many other papers which made valuable contributions to knowledge In his later years, indeed since *Caytonia*, he became increasingly pre-occupied with general problems, the origin of the Angiosperms, the nature of morphology, and indeed the philosophy of natural science, for his outlook was anything but restricted

Although an obituary in *Nature* of a distinguished scientist should deal mainly with scientific work we must also recall his deep appreciation of beauty, his gentle manner and his kind thoughtfulness.

Tom M. Harris

NEWS and VIEWS

The Russian Satellites *Vostoks 3* and *4*

The third Russian manned Earth satellite, *Vostok 3*, carrying Major Andrian Nikolayev, was launched at 08 30 h U T on August 11 The satellite, designated $1962\alpha\mu1$, entered an orbit inclined at 64° 59′ to the equator at 16 00 h U T on August 11 its orbital period was 88 32 min, the perigee and apogee heights being 180 and 234 km respectively At 08 02 h U T on August 12, *Vostok 4* ($1962\alpha\nu1$), carrying Lieut.-Colonel Pavel Popovich, was launched into an almost identical orbit. Initially, the two satellites were very close together, and Major Nikolayev saw *Vostok 4* through his porthole, but since the orbital period of *Vostok 3* was slightly lower, it slowly drew ahead of *Vostok 4*, at a rate of about 2 min a day At 18 00 h U T on August 12 the periods of *Vostoks 3* and *4* were 88 2 and 88 3 min respectively, their perigee heights 177 and 178 km, their apogee heights 228 and 235 km, and their orbital inclinations 64° 59′ and 64° 57′ On August 15 the two astronauts successfully returned to Earth, close to the intended point, south of Karaganda in Kazakhstan, within a few minutes of each other, at 06 55 and 07 01 h U T respectively

The flights of *Vostoks 3* and *4* mark several impressive new achievements in the development of space exploration Both Major Nikolayev and Lieut.-Colonel Popovich lived, slept and worked in conditions of weightlessness, apparently with efficiency and without ill-effect, for 4 and 3 days respectively, much longer than the 25 h of their predecessor Major Titov For the first time live television pictures of a man in orbit were publicly shown on Earth, and there was the first radio communication between men in space, as well as the first double descent from orbit The placing of *Vostok 4* into such close proximity with *Vostok 3* shows that a satellite can be launched into a specified orbit at a specified time, and the experiment goes a long way towards demonstrating the feasibility of a rendezvous between two spacecraft

Eightieth Birthday of Prof. James Franck

Prof James Franck, who celebrates his eightieth birthday on August 26, had his first great achievement fifty years ago, when he showed (with G Hertz, with whom he shared the Nobel Prize in 1926) that the energy loss of electrons in mercury vapour changed sharply at particular electron energies Here was direct evidence for the existence of quantum states in atoms, preceding Bohr's model of the hydrogen atom Atomic and molecular energy-levels remained Franck's field of study for another twenty fruitful years at the University of Göttingen, where he was professor and head of a flourishing school. many of his students from abroad became distinguished physicists (such as Blackett, Condon Oppenheimer, to mention a few) After 1933, though being a Jew, he could have stayed on because he had done distinguished service as an officer during the First World War But Franck preferred exile, first for a short time in Copenhagen, then in the United States There he devoted much of his effort—and still does—to the study of what is perhaps the most complicated and most important molecular process the photosynthesis of living material in plants For this work he was quite recently awarded a prize from the Academy of Gottingen

What distinguishes his work is his amazing physical intuition—rivalled only by people like Faraday and Rutherford—which has repeatedly enabled him to achieve penetrating insights with scarcely any use of mathematics or complex theories The 'Franck–Condon' principle', which explained many fine details in molecular spectra and which appeals directly to the imagination of the physicist, is a good example During the Second World War, Franck helped with the development of the atom bomb But when it was achieved he did his best—as chairman of a committee of scientists brought together for that purpose—to prevent its use and to forestall the arms race which he could foresee This is but one example of the deep humanity and unfailing kindness that have made him loved by everybody who knows him

Aviation at the Imperial College of Science and Technology : Prof. P. R. Owen

Prof P R Owen, who has recently been appointed to the Zaharoff chair of aviation in the Department of Aeronautics of the Imperial College of Science and Technology, is an eminent successor to the previous holders of this chair L Bairstow, A A Hall and H B Squire (see *Nature* obituary, 193, 421, 1962), who graced this important appointment Prof Owen graduated with an honours B Sc degree in aeronautics at the Queen Mary College in 1940 and worked afterwards in industry and the Royal Aircraft Establishment for a number of years While in the Royal Aircraft Establishment he became, in 1948, a principal scientific officer and head of the Fluid Motion Section, at which position he remained until 1953 After this period he joined the University of Manchester as a reader and director of the Fluid Motion Laboratory and was ultimately appointed professor of mechanics of fluid motion Prof Owen is well known for a number of significant contributions to the science and art of aeronautics His researches extend over a wide range of theoretical and experimental investigations, both so far as fundamental and practical problems are concerned Thus, he covered supersonic aerodynamics, where he proved during the War one of the pioneers in Britain, the mechanism of boundary layer transition, the laminar separation bubble on aerofoils and other topical aeronautical applications From 1953 onwards his interests became even more catholic and he investigated a number of fluid motion problems as far apart as hypersonic flow, turbulence, heat transfer, meteorology and such unusual sidelines as dust-transport in gas streams He is a member of a number of Government committees and well known as an inspiring teacher and leader of men He will, no doubt, broaden still further his research activities in the largest Department of Aeronautics existing in Britain at a university

Physical Chemistry at Southampton :

Prof Graham J Hills

Dr Graham J Hills, at present lecturer in the Imperial College of Science and Technology, has been appointed to the newly instituted chair of physical chemistry in the University of Southampton Dr Hills, who is thirty-six years of age, graduated from the old Birkbeck College in the City of London Having initially trained as an analyst, he undertook electrochemical research, as a London University Postgraduate Scholar, at that College and this work led to the now classical papers of Hills and Ives on the calomel electrode The association of these authors has continued over the past decade and is to be seen in the recent book *Reference Electrodes* Dr Hills left Birkbeck in 1949 to join the staff of Imperial College, first as assistant lecturer and then as lecturer in analytical chemistry On the departure of Dr Bockris, he transferred to physical chemistry and continued the long tradition of electrochemistry at Imperial College He extended the high-temperature investigations into molten salt systems and made a particular study of ionic mobilities by tracer-diffusion, conductance and polarographic techniques

During the period 1955–59, another comprehensive study was made of polyelectrolytes, ion-exchange resins and membranes, and in 1957 there began the present school of research into electrochemistry at high pressures This has involved the measurements at high pressures of electrolytic conductance, transport number, double-layer capacity and rate constant and is aimed at a better understanding of kinetic processes in condensed phases With considerable support from the Department of Scientific and Industrial Research and the Central Electricity Generating Board, these investigations are being extended to high temperatures, and this major undertaking is being launched at Southampton In 1959, Dr Hills was visiting lecturer in the University of Belgrade, and in 1961 visiting research associate in the University of Illinois For his published research in electrochemistry, he was awarded this year the degree of D Sc

The British Coal Utilization Research Association

Dr D T A Townend, C B E

Dr D T A Townend, director-general of the British Coal Utilization Research Association (B C U R A) for the past seventeen years, retires on September 30 During the First World War he served in the Royal Naval Air Service, afterwards he returned to the Imperial College of Science and Technology, where he was for many years associated with Bone and Newitt in research work on combustion problems, particularly at high pressures Towards the end of this period he elucidated the two-stage process of combustion of higher hydrocarbons and its relation to the problem of 'knock' in internal combustion engines In 1938 he was appointed to the Livesey chair of coal-gas and fuel industries in the University of Leeds and became associated with research work undertaken collaboratively between the University and the Institution of Gas Engineers (later the Gas Research Board), his research work also threw considerable light on the phenomena concerned with the stability of burner flames During the Second World War he was engaged on research problems for a number of Ministries, and as a scientific adviser to the Ministry of Home Security he made notable achievements in the field of incendiary warfare In 1945 he was invited to his present post During the War the B C U R A staff had been widely dispersed in temporary accommodation, and he was largely responsible for the present organization at Leatherhead Following nationalization, in 1947 the National Coal Board took the place of the Mining Association of Great Britain as the principal member of the B C U R A , membership by the other nationalized industries soon followed, and to-day much of the B C U R A 's work is supported by them, as well as by Trade Associations and other industrial concerns Dr Townend is a past chairman of the Committee of Directors of Research Associations and at present vice-chairman of the Parliamentary and Scientific Committee

Mr. D. Hicks

Dr Townend is to be succeeded by Mr D Hicks, now carbonization and scientific director of the East Midlands Division of the National Coal Board and director of the Operational Research Unit and Pneumokoniosis Research Unit of the Board He joined the staff of the Fuel Research Station in 1925 and was appointed officer-in-charge of the Cardiff Coal Survey Laboratory in 1929 In 1946 he was appointed national superintendent of the Coal Survey Organization with responsibility for co-ordinating the work of the eight Coal Survey Laboratories in the Coalfields In 1947 he was appointed director of scientific control of the National Coal Board The responsibilities of this post included the direction of the Coal Survey Laboratories and the creation of a Scientific Service in the coalfields He was also responsible for forming the Board's Operational Research Group and for the scientific programme of the Pneumokoniosis Field Research Unit Mr Hicks is also chairman of the Research Committee of the British Coke Research Association, of the International Standards Organization (Solid Mineral Fuel Committee) and of the B C U R A Domestic Appliances Committee and a member of Council and of the Research Committee of the Coal Tar Research Association He is a Fellow of the Institute of Fuel and of the Royal Institute of Chemistry

Mr R L Brown

Mr R L Brown, director of the B C U R A 's Basic Research Laboratories since 1950, has been appointed deputy director-general Mr Brown won an open scholarship in mathematics to Trinity College, Cambridge, in 1934 and was a wrangler, taking a first in Part 2 and passing with distinction Part 3 of the Mathematical Tripos He joined the B C U R A in 1938 and was appointed head of the Mathematics and Mechanics Department in 1946 and superintendent of the Physics Department in 1949 He is a Fellow of the Institute of Fuel and of the Institute of Physics and was awarded the Students Medal of the Institute of Fuel in 1939 He is a member of the Publication Committee of these Institutes and was chairman of the Organizing Committee of the Institute of Fuel Conference on "Science in the Use of Coal", and from 1956 until 1960 was honorary secretary of the Committee of Directors of Research Associations He, and Mr Hicks, will take up their new posts on October 1

Great Britain and Space Research

IN a written answer in the House of Commons on July 30 the Minister of Aviation, Mr J Amery, stated that the United Kingdom, together with Australia, Belgium, France, the Federal Republic of Germany, Italy and the Netherlands, was participating in the development of a three-stage satellite launcher by the European Launcher Development Organization A preparatory group had been set up to co-ordinate the work proceeding in the member countries, pending the ratification of the Convention to establish the Organization A technical mission was at present in Australia examining the problems connected with firing the *Blue Streak* first stage and the three-stage launcher from the Woomera Range The Postmaster-General, Mr J R Bevins, stated on July 31 that the Post Office expected to spend about £700,000 in 1962–63 on the development of communications by means of artificial satellites, and tentatively provision of £1 million was provided in each of the next four years

On August 2 it was stated by Lord Hailsham in the House of Lords and by the Parliamentary Secretary for Science in the House of Commons that a Space Research Management Group was set up under the Office of the Minister for Science, with effect from May 1, 1962, which had assumed the responsibilities for the management of the programme of experiments in rockets and satellites, previously discharged under *ad hoc* arrangements by two scientists and one engineer on loan to the Royal Society from the public services The new Group would comprise these three officers, five additional officers and supporting staff This is an *ad hoc* arrangement pending the outcome of the present inquiry into Government and scientific organization and had been introduced in agreement with the Royal Society The British National Committee on Space Research, set up by the Royal Society, would continue to advise on the scientific content of the programme and the Steering Group on Space Research would continue to advise the Minister on policy matters in its field In the House of Commons, Mr Freeth added that the massive flow of coded data from the satellite *Ariel* would take time to process and analyse Those concerned with the experiments were not yet ready to express considered views although they had indicated that much interesting and valuable information about the structure of the ionosphere and the constitution of the high atmosphere was now available Recently, transmission of data had been interrupted irregularly and the reason for this was being investigated

Nuclear Power Reactors in Britain

IN written replies to questions in the House of Commons on July 31, the Parliamentary Secretary for Science, Mr D Freeth, stated that the Atomic Energy Authority had spent about £10 million on the development of beryllium as a canning material for advanced gas-cooled reactor fuel Including supporting services, 630 people were employed on the Dounreay fast reactor Comprehensive inspection during the five and a half years since the first nuclear power station at Calder Hall came into operation had given no evidence that the life of magnox stations would be limited to 20 years, there was as yet no final proof of the life of a reactor, but an assumption of 30 years could be as realistic as 20, particularly for the later stations in the programme

Professional Qualifications and the European Community

IN a debate in the House of Lords on Britain and the Common Market on August 1, Lord Cohen of Birkenhead directed attention to the implications of the Treaty of Rome for all those professions which require a qualification registrable by law Section 1 of Article 57 empowers the Council to issue directions regarding mutual recognition of certificates, diplomas and other qualifications Lord Cohen was concerned that in consequence a medical or other professional qualification obtained in any of the member States of the European Economic Community would be acceptable as a criterion of a registered medical practitioner Although vice versa British qualifications would be recognized by the 'Six', Lord Cohen said that on account of the wide disparity in standards of medical qualification and practice among members of the European Economic Community this Article had given rise to grave disquiet in the medical, dental and para-medical professions in Britain Lord Cohen entered no claim for any sectional interest but was concerned at the effect on the public interest of any debasing of professional standards In replying on the debate, the Lord Chancellor pointed out that the Council of Ministers could only issue directives for the mutual recognition of qualifications on proposals made to them by the Commission and after consulting the European Assembly Such directives had no effect for the medical, para-medical and pharmaceutical professions, until conditions for the exercise of these conditions had been co-ordinated Further voting on these matters must be unanimous and he thought that these were substantial safeguards The Government understood the importance of this subject, and if Britain joined the Community the Government would keep in close touch with the General Medical Council and all other interested bodies, while playing her part in the Community's proceedings Regard would be had, as the General Medical Council had urged, to the standards achieved in Britain

The Commonwealth Development Corporation

THE Minister of State for Colonial Affairs, Lord Lansdowne, announced in the House of Lords on July 31 that it had been decided to extend the activities of the Colonial Development Corporation which have hitherto been confined to dependent territories It is proposed henceforth to authorize the Corporation to undertake new development schemes in countries in which it was previously empowered to operate even after they have become independent members of the Commonwealth The

Corporation will be renamed the Commonwealth Development Corporation The necessary legislation will be introduced as soon as possible A similar statement was made simultaneously in the House of Commons.

M R C. Committee to study the Methodology of Toxicity Testing

In reply to a question in the House of Lords on August 2, the Minister for Science, Lord Hailsham, said that the Minister of Health sought advice on testing new drugs generally through his Standing Medical Advisory Committee, which was the appropriate body Since the recent events relating to thalidomide, Lord Hailsham said he had himself inquired of the Medical Research Council concerning the part it could expect to play in advancing methods of testing The Council had that week announced its intention to appoint a committee, under the chairmanship of Sir Charles Harington, to study the methodology of toxicity testing Lord Hailsham attached great importance to the work of this Committee, although it was not the Medical Research Council's responsibility to carry out routine testing programmes on drugs or other chemicals from the point of view of either efficiency or toxicity It did, however, sponsor many clinical trials of new preparations of particular promise for specific purposes and had for many years undertaken fundamental toxicological research, especially with regard to the difficult methodological problems which arise in devising tests to demonstrate possible long-term effects which might be produced, for example, by food additives The Council had a special responsibility for advising the Minister of Health on the scheduling of drugs under the Therapeutic Substances Act. So far as thalidomide was concerned, he was advised that there was general agreement that in the existing state of knowledge it was extremely unlikely the most rigorous programme of screening tests would have suggested an effect was to be expected on the developing human embryo

U S. National Committee for the International Council for Building Research, Studies and Documentation

The National Academy of Sciences–National Research Council has announced the organization of a U S National Committee for the International Council for Building Research, Studies and Documentation The Academy–Research Council was requested to become the official adhering body for the United States instead of the Housing and Home Finance Agency in order to broaden and strengthen participation by the United States in the activities of the International Council As a non-governmental organization, the International Council for Building Research, Studies and Documentation promotes international co-operation in its areas of interest and is concerned with not only the technical but also the social and economic aspects of building Membership in the U S National Committee includes representatives of nine national organizations and five federal agencies, provisions have also been made for additional representatives and three members-at-large No chairman has yet been named The Committee will be administered within the Division of Engineering and Industrial Research of the Academy–Research Council Staff support is being provided through a Secretariat consisting of an executive secretary, Mr Robert M Dillon, and a technical secretary, Mr Robert W Spangler Further information can be obtained from the executive secretary, U S National Committee for CIB, National Academy of Sciences–National Research Council, 2101 Constitution Avenue, N W, Washington 25, D C

Leicester Museums and Art Gallery

It is seldom that a provincial museum can finance the publication of a list of figured and described material in its geological collections This has recently been accomplished by the Leicester Museums and Art Gallery, which has published *A Catalogue of the Figures and Cited Specimens in the Department of Geology, 1962* (Pp 46 Leicester The Museums and Art Gallery, 1962). The list has been compiled by the curator of geology, C A Sizer, who, in an introduction, rightly stresses that the formative period of the collections covers a long time In spite of different curatorial standards through the decades, it has been possible to list a large number of specimens A few are holotypes, a few more are figured, but the great majority are cited, though mentioned is the term more generally used These lists will be of service to palæontologists, especially those working in the Leicester area, and, although the information is of a negative character, it is of value to know that unfortunately certain specimens have been lost The publication also includes a few petrological specimens and the relevant references

Refraction of the Eye and its Components in Twins

Two earlier monographs by Prof Arnold Sorsby *et al* have established that relatively few cases of long sight and short sight are the result of anomalies in the dimensions of the optical components, for the most part, these are within the normal range but are inadequately correlated Three questions thus arise First, what determines the anatomical anomaly seen in the 3–5 per cent of the population who have 'component' ametropia? Secondly, what causes 'correlation' ametropias which are seen in some 55 per cent of the population and which represent varying degrees of failure, during the growth of the components, of a physiological co-ordinating mechanism ? Finally, how do the 40 per cent or so who are emmetropic come to have perfect correlation ? A new investigation carried out by Prof Sorsby, M Sheridan and G A Leary on twins is an attempt to assess the significance of heredity in the determination of these three types of refraction (*Medical Research Council Special Report Series*, No 303 *Refraction and its Components in Twins* Pp viii + 43 London H M S O , 1962 7*s* net) It is based on an analysis of data not only concerned with refraction as a whole but also on the individual optical components For both refraction and its components, uniovular twins in all the refraction groups were found to show a significantly higher incidence of concordant values than biovular twins and unrelated pairs Such discordance as was found in uniovular twins was of the same order as that known to occur with many morphological features, and which is generally regarded as due to variation in the expression of the genes rather than to environmental influences. It may therefore be taken as established that the dimensions of the optical components, the efficiency of the mechanism co-ordinating the growth of the components, and thus the refraction of the eye, are all genetically determined The modes of inheritance and the possibility that environmental factors have a minor modifying influence are the principal problems now awaiting clarification

The Institution of Electrical Engineers

THE following officers have been elected to the Boards of the Institution of Electrical Engineers' new Divisions, which will replace the former Specialized Sections on October 1 *Electronics Division Board*, Mr. J A Ratcliffe, director of the Department of Scientific and Industrial Research, Radio Research Station at Slough (chairman), Mr G G Gouriet (deputy chairman), Dr R C G. Williams and Mr. A J Young (vice-chairmen) *Power Division Board*, Mr D B Irving, chairman of the London Electricity Board (chairman), Mr C. D Wilkinson (deputy chairman), Mr C H Flurscheim and Mr D T. Hollingsworth (vice-chairmen) *Science and General Division Board*, Dr D Taylor, co-ordinator of research and development for the Plessey Group of Companies (chairman), Dr J R Mortlock (deputy chairman), Mr. C G Garton and Prof J M Meek (vice-chairmen)

Sixth-Form Biology in the Future

A CONFERENCE on sixth-form biology is to be held by the Joint Biology Committee, in the Senate House, University of London, on November 10 Interest will be directed less to details of syllabuses than to considerations which are in keeping with contemporary progress in biological science and the flow of educational thought Those taking part include Dr. L M J Kramer, senior biology master, Eton College, Miss M Going, headmistress, Church of England College, Birmingham, Miss B G Ashton, head of the Science Department, Edgbaston High School, Birmingham, Mr P Kelly, head of the Biology Department, Bexley Grammar School, Dr J T Aitkin, reader in the Department of Anatomy and Embryology, University College, London, and Dr C D Pigott, lecturer in the Department of Botany, Cambridge Further information can be obtained from the Association of Agriculture, 36 Victoria Street, London, S W 1

Nuclear Studies at the Liverpool College of Technology

THE prospectus of post-graduate courses and research in nuclear studies to be held at the Liverpool College of Technology during the 1962–63 session is now available The programme again includes the well-established series on "Radiation Safety and Health Physics" These courses, which have received the full support of the United Kingdom Atomic Energy Authority Health and Safety Branch, are of seven months and two weeks duration The long course leads to a College Diploma in Health Physics and has been recognized by the Department of Scientific and Industrial Research as suitable for the tenure of its advanced course studentships Two-week courses in radiobiology and one-week courses in radiation chemistry and radiometric analysis are also being offered The prospectus is available from the principal lecturer in nuclear studies, J W. Lucas, City of Liverpool College of Technology, New Building, Byrom Street, Liverpool 3

Burroughs Wellcome Research Fellowships

THE Australian Academy of Science is inviting applications for Burroughs Wellcome fellowships Awards will be made in such a way that there are not more than three fellowships occupied at any time, each tenable for two years The fellowships may be awarded in any branch of medical sciences. They must be occupied in one of the following professorial departments of an Australian university medicine. psychological medicine, preventive medicine, experimental medicine, pediatric medicine (child health) pharmacology, or pharmaceutical science Applicants should, in general, hold the Ph D degree or have equivalent status and experience Preference will be given to applicants who are under the age of 30 years on July 1 in the year in which the application is received The fellowships are valued at £2,000 per annum There is no printed form of application Each applicant will be required to state the general nature and scope of the research he wishes to undertake, and the university department which is prepared to accept him He should submit copies of scientific papers that he has already published and should furnish the names of three referees who can speak from personal knowledge of his capacity for research Applications, which will close on September 30, should be sent to the Assistant Secretary, the Australian Academy of Science, Gordon Street, Canberra City, A C T

Announcements

THE death is announced from Stuttgart of Dr Otto Fauser, a Regierungsbaudirector of the pre-war German Reich, a well-known member of the older group of soil scientists, and a regular and enthusiastic participant in their conferences and excursions

MR T L BIRRELL has been elected president of the Plastics Institute for 1962–63 At present, Mr Birrell is a part-time director of Yarsley Research Laboratories, Ltd He was one of the original signatories to the British Plastics Moulding Trade Association (the forerunner of the British Plastics Federation) and was chairman of the Plastics Institute in 1942–43, and president for one year in 1952–53

THE Bradford Institute of Technology is holding a short course for graduates on "Polymer Structure and Properties" during November 2–3 Lecturers include Dr C W Bunn, Dr L B Morgan, Dr A Keller, Dr I Goodman and Dr M Gordon Further information can be obtained from Dr W R Moore, Department of Chemical Technology, Bradford Institute of Technology, Bradford 7.

THE Congress on the History of Pharmacy at the University of Nottingham, a notice of which appeared on p 546 of the August 11 issue of *Nature*, has been postponed and will now be held during September 20–23, 1963 In its place, the third British Congress on the History of Medicine will be held in London during September 26–28, 1962, the theme of which is "The Evolution of Hospitals in Britain" Further information can be obtained from Dr. F N L Poynter, Wellcome Historical Medical Library, the Wellcome Building, Euston Road, London, N W 1

ERRATUM In the article entitled "Effect of Strain and Group Size on the Response of Mice to 'Seconal' Anæsthesia", by J H Mackintosh, which appeared on p 1304 of the June 30 issue of *Nature*, the numbers of animals used in the experiments have been omitted Each figure in Table 1 represents at least 27, but usually about 40 mice

DENTAL HYGIENE AND FLUORIDATION OF WATER

NEARLY fifty years ago two American dentists directed attention to a condition of the teeth, characterized by unsightly mottling of the enamel, which occurred in the inhabitants of certain well-defined areas The cause of this abnormality was later shown to be the presence of fluoride in the drinking water, the topographical distribution of cases being due to variations in naturally occurring fluorides in the water in different localities Lesions occurred only in persons who had been exposed as children to fluoride-containing water and did not occur in adults who had passed their childhood elsewhere The proportion of persons affected, and the extent of the lesions, were shown to vary directly with the concentration of fluoride in the water Later, it was found that though the enamel could be so severely affected that the teeth appeared to be quite badly damaged, they were at the same time much less susceptible to dental caries than were normal teeth These findings were confirmed in many subsequent investigations, and it has now been established that concentrations of fluorine salts of more than 1 0 part per million in drinking water may lead to the appearance of enamel lesions and also to increased resistance to caries At this level, however, the lesions are minimal and very few persons are affected With increasing concentrations the lesions become more pronounced and more members of the population show them Nevertheless, the resistance to caries which was found to be associated with the presence of very obvious lesions is still present when the level of fluorides in the drinking water is so small that only very occasional lesions of minimal proportions occur in a few people Investigations in the United States have shown that the degree of this resistance is such that children born and brought up in areas with 1 0 p p m of fluoride occurring naturally in the water have up to 60 per cent less dental caries than children brought up in areas where there is only a trace of fluoride in the water

Further investigations in the United States ,and Canada showed that the addition of fluoride to water sufficient to raise the fluoride content to 1 0 p p m had the same effect on the incidence of dental caries as water with naturally occurring fluoride As a result of these findings, a British mission to the United States and Canada in 1952 recommended that fluoride should be added to the water supplies of selected communities in the United Kingdom, as a pilot study The Ministry of Health report, *The Conduct of the Fluoridation Studies in the United Kingdom and the Results Achieved after Five Years**, now gives the results of these investigations carried out in Watford in part of Anglesey and in Kilmarnock Andover was originally designated as a fourth study area, but fluoridation was discontinued by the local authority after two years

The report gives details of the carefully controlled investigations which have now been in progress for five years Only the findings for the deciduous teeth of children aged 3–7 years are given, since the full effect of fluoride is only exerted when it is absorbed continuously during the whole period of tooth formation and calcification The data show that whereas prior to fluoridation in 1955–56 children aged three years had on average 3 80 carious teeth, the figure for this age in 1961 was 1 29 The corresponding figures for four-year-old children were 5 39 and 2 31, and for five-year-old children 5 81 and 2 91 These figures represent reductions of caries incidence of 66 per cent, 57 per cent and 50 per cent respectively There was also a reduction of incidence of caries in the control areas, but only in the region of between 2 and 7 per cent In children of six and seven years, some of whose teeth were already calcified before fluoridation commenced, the reduction of caries was of a lesser degree

In addition to these striking figures, the report deals with the question of the safety of fluoridation and also gives some details of the technical problems involved in the fluoridation of public water supplies With regard to possible toxicity, the fullest investigation of all available evidence has been made and it is concluded that no harm results from raising the fluoride content of drinking water to 1 0 p p m This agrees with the opinion of the World Health Organization's Expert Committee which, after examining the evidence, concluded that "All these findings fit together in a consonant whole that constitutes a great guarantee of safety—a body of evidence without precedent in public health procedures"

This century has witnessed many triumphs of preventive and curative medicine It is clear that this short report embodies yet another R B LUCAS

ICARUS

A NEW journal, entitled *Icarus*, has recently been published* It is yet another of those intended to serve a part of that enormous new field of scientific activity popularly known as 'space research' According to the editors it is to deal with "the new interdisciplinary science of the solar system—which is emerging to claim its own identity at the cross-roads of the allied disciplines of astronomy, geology, geophysics, meteorology, geochemistry, plasma physics, and biology" Their aim is "to make a positive contribution to the cause of scientific communication in three distinct ways

"(*a*) by a selective concentration of subjects which would otherwise have appeared in a variety of widely scattered scientific periodicals to establish a large-signal, low-noise channel for information on most scientific aspects of the solar system,

---

* *Icarus*, Vol 1, No 1 (May 1962) International Journal of the Solar System Edited by Z Kopal and A G Wilson Pp 93 Subscription rates (Vol 1, 6 issues) Institutional subscribers, 18 dollars, Private subscribers certifying that the journal is for personal use, 10 dollars (New York and London Academic Press, Inc , 1962)

"(*b*) by minimizing delay between the receipt of a communication and its publication to effect the promptness of communication essential in a so rapidly developing field of science,

"(*c*) by inclusion of a bibliographical section covering all fields of interest to investigators of the solar system to ease the task of monitoring the information"

There are 35 associate editors, most of whose names are already well known Their function is to collect papers and also to act as referees It remains to be seen whether this arrangement will prove more successful than that of anonymous referees whom we all find reasonably efficient in dealing with the papers of other authors, although so tiresome with our own

Fantastically great resources are at present being devoted to space research, but most of the effort is still being channelled into elaborate and lengthy preparations for difficult experiments, of which comparatively few have yet had time to produce results If all goes according to plan, ultimately, the amount of new material to be published and discussed may be very great But so far, relative to the scale of the effort, the volume of results to reach the stage of publication is small (although this is not to minimize their significance) Clearly, *Icarus* has been started in the expectation of taking part in the harvest, but in common with other similar journals it must, for the present, rely chiefly on papers that could equally well have appeared in one or other of half a dozen existing periodicals This at least seems true of *Icarus*, 1, No 1 It contains a long paper by A G W Cameron discussing the problem of the formation of the Sun and planets, and three much shorter papers on the interplanetary medium, on the behaviour of photoelectrons emitted by solid bodies such as the Moon, and about the blue haze on Mars There is also a letter discussing toroidal oscillations of the Moon

Science is to-day more than ever in danger of sharing the fate of the Tower of Babel However, the editors of *Icarus* believe that continued progress can be ensured by the formation of fresh, specialized sub-groups, each drawn from a fairly wide field of existing studies and provided with its own specialized journals This kind of approach is not exactly new. it has been fruitful in the past and perhaps it promises better than any other We are in a period of excessively rapid change in astronomy and in every other science connected with space research, affecting theories, instrumentation, administration, and ideas of all kinds, so that it is very difficult to say with confidence what policies are wisest But so far as publications are concerned, I question whether existing journals are so overloaded that they cannot absorb comfortably all the papers on astronomy likely to result from space research for at least two or three years yet By then we may be able to see the needs of the situation more clearly

The financial problems of existing journals are not negligible, and the extra support of space research papers, should it lead to a greater circulation, as it probably would, might in most cases be very welcome Further, I think it important that space research workers should know what is going on in the older astronomy, and that equally the older kind of astronomer should get to know about space research Ten or fifteen years ago, after some initial fumbling, radio and optical astronomers discovered that they were better off together than apart, and now to a large extent publish their papers together in the same journals I hope that this kind of development will come about in the case of astronomy conducted with rockets, artificial satellites, etc

As to rapidity of publication, the average interval between receipt of manuscript and publication is slightly greater in *Icarus*, 1, No 1, than in *Monthly Notices of the Royal Astronomical Society*, **124**, No 1, also dated May 1962, a journal now 135 years old. which still manages to cover most of astronomy at a satisfactory level of originality and technical quality

The bibliography mentioned by the editors include 349 papers in this issue, the great majority from astronomical journals They are classified, but no abstracts are given Policy for this section of *Icarus* is still fluid, and one must wait for further issues before being able to judge whether there will be a distinctive service not yet provided by existing abstracting journals

R O REDMAN

PLANNING NEW COMMUNITIES IN BRITAIN

THE report of the Carnegie United Kingdom Trust for 1960 gave some account of the study of the social problems of new communities in Britain which Dr J H Nicholson had made at the request of the Trust and of the National Council for Social Service, and stated also that the Trust had set aside £100,000 in the new quinquennium, which opened in 1961, in order to promote pioneer projects in the provision of social amenities in new communities The Trust has also appointed an Advisory Committee to consider applications, and where appropriate, to initiate action Up to the end of 1961 no project, however, had been brought to the point of qualifying for a grant from this fund, practically all failing to measure up to the required standard of innovation The fund is reserved for assisting work that is now on a national scale, and the Trust is prepared to wait for the right projects It is hoped that by the end of 1962 a pattern of expenditure will be planned which will provide assistance for promising projects in one or more of each type of new community in different geographical regions

Dr Nicholson's report was published in August 1961 *, and the importance attached by the Carnegie United Kingdom Trust to this work is well indicated by the fact that in its report for 1961 † the Trust includes Dr Nicholson's general recommendations *in extenso* as well as those on social development His report is concerned with the new communities on housing estates, in the fifteen new towns, in the planned extensions to certain small towns, and in the new housing estates built to replace slums now being demolished in the central areas of most large cities Dr Nicholson directs most attention to the new towns, considering their housing problems and those of employment and services in separate chapters, and to the new towns as communities in a third chapter Then he compares the four types of new communities and discusses the problems of community and leadership, assessing the factors which encourage the development of leadership and sources from which leaders are drawn

---

* *New Communities in Britain Achievements and Problems* By J H Nicholson Pp 191 (London The National Council of Social Service, Inc , 1961) 10*s* 6*d*

† The Carnegie United Kingdom Trust 48th Annual Report, 1961 Pp viii+76 (Dunfermline, Fife The Carnegie United Kingdom Trust, 1962) (See also *Nature*, **195**, 338, 1962.)

These two chapters with their constructive suggestions as well as critical analysis are probably the most valuable part of the report, though Dr Nicholson's clear account of the actual achievements, as well as his lucid assessment of the situation, should contribute to the public understanding of the real situation and needs of the new communities Such an understanding, free from party political bias, is an almost indispensable pre-requisite to the formulation of the kind of proposals which the Carnegie Trust awaits

For the rest, the general content of the report is well indicated by Dr Nicholson's actual recommendations, which, as already noted, fall into two groups Taking the general recommendations first, the new towns are producing a new type of community, and this is likely to be true also of many expanded towns For social provision generally, these new communities will be unable easily to draw on the resources of personnel or material of the local authorities of the towns from which the population is being exported Dr Nicholson recommends accordingly that the needs of the newcomers rather than the existing fractions of the town or county should be the dominant consideration A balanced community, with the optimum degree of self-containment, should be envisaged from the start and be the guiding principle in policy and planning Future plans should provide for an adequate balance of age-groups, and if this cannot be achieved initially, the master-plan should provide for the building of the necessary accommodation to redress the balance later An adequate variety of types of accommodation to offer an effective choice between houses, maisonettes and flats is recommended, and to allow the possibility of purchase where desired The policy of providing employment with housing should be continued and extended, including further new towns and the possibility that one of the larger local authorities, or two of them jointly, might build a new town

Since the social structure of a community depends on the balance of occupations, a variety of industries and other kinds of employment should provide work for skilled and unskilled men, for women (full-time and part-time), and in particular, for juveniles Employment in commerce, offices, service, industry and shops, and in professional occupations is especially important It could be questioned whether the report takes account of long-term trends in employment, particularly the diminishing amount of unskilled labour that is likely to be required, and although this really lies outside the scope of Dr Nicholson's inquiry, the social effects of technological change certainly require careful study in the light of the needs of new communities Beyond this, Dr Nicholson recommends that the master-plan should provide for a town centre adequate to the needs of the community when fully developed, and the provision of services—including meeting-places and other amenities—should be related to the neighbourhoods and other planning units The master-plan should also provide sites for natural expansion, for churches, meeting-places, public houses and places of entertainment in each section These and adequate space earmarked for physical recreation, should be protected against 'infalling' with housing unless a comprehensive survey of social requirements shows they are no longer needed for social purposes

Nine recommendations on social development follow First, services and amenities should be provided concurrently with the houses, and great stress is laid on the need for the closest co-operation between the country and the developing authority as to provision and timing The need for community services, outside the scope of the statutory services, should be kept under constant review by statutory and voluntary bodies Provision should also be made ahead of needs for a meeting-place suitable for small groups, capable of extension if and when larger accommodation is needed and the necessary finance to build and maintain has been secured Community development should be fostered in various ways by canalizing action from representative bodies such as community associations, appointing a social development officer in every new town and large estate, and neighbourhood workers in smaller estates, by placing housing management in the hands of qualified officers able to make personal contact with tenants, establishing as soon as possible the normal range of social agencies, voluntary as well as statutory, providing in larger communities a joint centre for social workers with offices, meeting-room and shared services, and making every effort to elicit leadership from within the community itself

Further close consideration and experiment should be directed towards discovering the types of provision—typically in clubs—most likely to attract and hold adolescents, and use should be made of the experience of social workers trained in group work Community and neighbourhood associations are making a major contribution to many new communities, particularly by providing in their centres a wide variety of leisure activities, and in the experience they give in the techniques of democratic self-government and leadership The associations and their National Federation should continue to review the organization and policies of the movement in the present situation in new communities, in particular considering how the needs of the communities they serve can best be ascertained and met, continuing and extending the training of full-time community centre wardens and part-time voluntary officers The Churches should keep continually under review the balance between their own social activities and the work of their members in the wider community Close touch should be kept between the various authorities and agencies concerned in social development at officer-level and those appointed to special duties in this field should be consulted from the planning stage onwards The participation of the general community should be secured at local level through the community or neighbourhood association and at central level through a council of social service Further field surveys dealing with particular communities and particular problems are needed It is hoped that the bodies which have sponsored and financed studies of social development will continue to do so, and that other bodies will join them in making possible the further exploration of this wide and important field

EARTHQUAKE SWARM IN CHILE BEGINNING IN MAY 1960

BEGINNING in May 1960 and continuing with lesser intensity throughout the succeeding months a violent earthquake swarm ravaged large areas of Chile between latitudes 36° S and 48° S The readings obtained by Mr E F Baxter at the University of Durham Seismological Observatory were as shown in Table 1 The swarm was accompanied by a major eruption of the volcano Puyehue and by a tremendous sea wave (Tsunami) which extended from Chile to the most distant parts of the Pacific Ocean About 500 deaths from the effects of the earthquakes in Chile are known, and probably in the same country more than 1,000 died in consequence of the Tsunami Thousands of people were injured and recovery from property damage is even now not complete D Pierre Saint-Amand has recently published a vivid account of the happenings in Chile at the time[1]

Local investigations have been undertaken by the Chilean Geological Survey under the direction of Don Carlos Ruiz, by the Escuela de Geologia (University of Chile) under the direction of Don Humberto Fuenzalida, by the U S Geological Survey, by the University of California and by other organizations Instrumental data were obtained throughout the world

The first large shock of the swarm came about 6 a m local time on Saturday, May 21, 1960, with epicentre in the peninsula of Arauco, just south of Concepcion near the town of Curanilahue The damage was largely in the city of Concepcion and in the coal-mining towns of the Arauco Peninsula There was also some damage to towns in the central valley Shocks continued on Saturday and Sunday throughout southern Chile and people, being afraid, were fortunately out of doors when the 'Remezon' struck This was at about 3 15 p m local time Dr Saint-Amand reports that the motion of the ground then was slow and rolling like that of the sea during a heavy swell Parked cars in Concepcion rolled to and fro through a distance of ½ m and bobbed up and down The tops of the trees waved as in a tempest Buildings crashed The period of vibration of the ground is reported to have been of the order of 10 sec or more and the visible duration of the motion some 3½ min In the region of the lakes, at Llifen, a similar movement began smoothly and continued for about 2 min when, suddenly, a loud noise was heard underground This was followed by a sharp jarring motion and a more rapid, less regular, vibration of the earth Other places reported similar movements The seismograph at Concepcion was unhinged by the first shock, but the instruments at Santaigo continued recording It was clear that Chile was being subjected to a major earthquake swarm, and that the active area was about 160 km wide and 1,600 km long in southern Chile

About 20 min after the greatest earthquake on May 22, following an initial retreat of the sea from the land, the sea returned, advancing with tremendous force on the shore in a wave that was in some places more than 20 ft high The water rushed over the land doing very great damage The damage was especially great on the Island of Chiloe, and the maximum height of the principal wave in Chile appears to have occurred between Puerto Saavedra and Bahia Mansa Following this were several successive waves The waves, beginning near the coast of southern Chile, proceeded in all directions over the surface of the Pacific Ocean with a velocity of about 700 km/h, not only along the coast of Chile but to the shores of Hawaii, New Zealand, Australia, Japan and Kamchatka, causing damage in all these places The maximum height of the waves in Hawaii was at Hilo (35 ft), and in Japan north-east of Hondo (18 ft)

Between 1 30 p m and 2 45 p m local time on May 24, 1960 (some 47 h after the main earthquake), the volcano Puyehue erupted explosively, sending out a cloud of ash and steam to a height of about 20,000 ft The eruption, which was from a fissure about 300 m long on the north-west flank continued for several weeks The ash eruption was followed by a discharge of viscous lava, making several flows about 1 km long The lava was no longer in motion on July 22, 1960

Very little permanent surface faulting has been observed following the earthquakes, but it is probable that the first earthquake had its focus on the Arauco fault plane near Curanilahue at considerable depth Movement probably next took place at the Reloncavi fault, and later movement along a series of other faults in the central valley and along the coast ranges, giving rise to after-shocks The changes in elevation of the coastline and islands (maximum about 6 ft) seem to indicate movement along a fault between Guafo and Mocha Islands and the coast The whole fault movement began in the north and progressed southwards Recent work by Aki using Rayleigh waves indicates that the after-shocks of the earthquake took place on dextral strike-slip faults provided we assume the faults to run parallel with the coast The total length of faulting for the whole swarm probably extended to more than 1,200 km

The considerable flooding after the earthquakes was not only due to the tectonic movement altering watercourses, but also to the Tsunami, which blocked the mouths of rivers and streams with mud and sand

Landslides, occasioned by the earthquakes, also dammed many rivers, especially those swollen by heavy rain

The region affected by these earthquakes has been similarly affected in the past Dr F Greve of the seismological institute at Santiago has summarized his own work and that of Montessus de Balore Between the years 1520 and 1946 there were 47 notable earthquakes in southern Chile, together with millions of minor ones Seven of these shocks probably attained a magnitude (8 4) similar to that of May 22, 1960, and eight shocks probably had Tsunamis associated with them In 1575 an earthquake had a similar zone of influence, even to having produced a large landslide in Rio San Pedro

EFFECT OF OXYGEN ON THE ELECTRON SPIN RESONANCE LINE-WIDTHS OF AMORPHOUS CARBONS

By J. W. C SPACKMAN

Physics Branch, Royal Military College of Science, Shrivenham

THE electron spin resonance absorption of the carbon blacks has frequently been ascribed to free radicals Recent work indicates, however, that it is due to charge carriers Thus the line shapes corresponding to a fast diffusing paramagnetic species can be obtained from compressed samples, and such modified spectra cannot be explained in terms of free radicals Work on this topic is in progress The present article is concerned with discussing the variation of line-width with oxygen pressure in the light of this observation The line-width of carbon blacks and other carbonaceous materials has been shown to vary linearly with oxygen pressure over a fairly wide pressure range[1-3] The results obtained for a series of commercial carbon blacks is shown at Fig 1 The curves are linear down to pressures of < 1 mm and these results show no sign of departure from linearity due to absorbed oxygen as has been reported by Tikhomirova *et al* [1] working on sugar carbons The curves show an interesting 'fanning-out' effect, that is, those with the greatest line-width at zero oxygen pressure have also the greatest slope

These effects can be semiquantitatively explained on the theory of Dyson for the spin resonance absorption of conduction electrons[4] Dyson proposes that the total relaxation time T_2 (where T_2 is the inverse line-width) in particles small compared with the skin depth is given by an expression of the form

$$\frac{1}{T_2} = \frac{1}{T_B} + \frac{1}{T_S} \tag{1}$$

where T_B is the bulk relaxation time and T_S is a surface relaxation time, which, in the absence of oxygen, is given by an equation

$$T_S = \frac{4}{3}\frac{r}{\varepsilon v} \tag{2}$$

where r is the particle radius, ε is the probability of spin disorientation during the surface collision and v is the velocity of electrons at the top of the Fermi surface For pure metals T_S is large compared with T_B and its effect may be ignored, but in collision with an impure irregular surface an electron is subjected to strong spin dependent forces due to surface irregularities or to paramagnetic surface impurities and the effect of T_S may be considerable It is in fact likely to be preponderant

Now in the presence of oxygen an additional term must be added to the expression for the surface relaxation time, that is

$$\frac{1}{T_S'} = \frac{1}{T_S} + \frac{1}{T_{O_2}} \tag{3}$$

where T_S' is the surface relaxation time in the presence of oxygen, T_S is the relaxation time in the absence of oxygen and T_{O_2} is a term introduced to account for the increased probability of spin disorientation due to oxygen By analogy with equation (2) T_{O_2} will be given by an equation

$$T_{O_2} = \frac{4}{3}\frac{r}{\varepsilon_{O_2} v} \tag{4}$$

where ε_{O_2} is the probability of spin disorientation at the surface due to the presence of oxygen Now

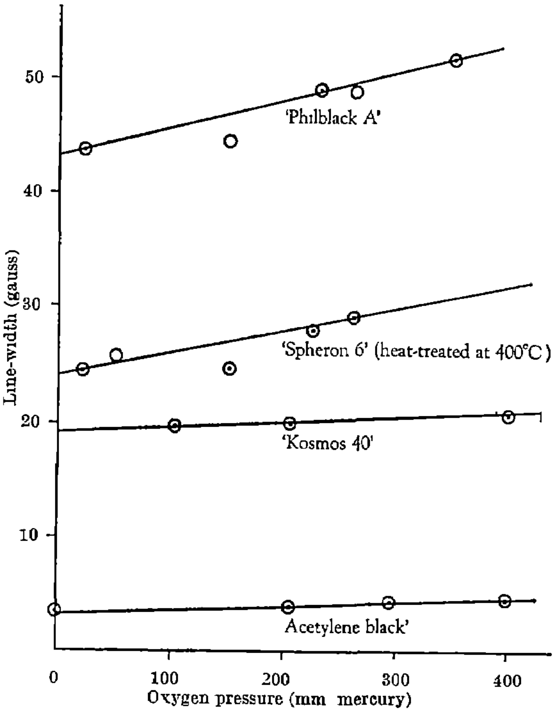

Fig 1 Variation of line-width with oxygen pressure

it is reasonable to suppose that ε_{O_2} is proportional to the concentration of paramagnetic gas molecules above the surface and to a surface factor representing the ease with which spin interaction can take place between the spin of an oxygen molecule and an unpaired spin in the material Thus if p is the pressure of oxygen above the material

$$T_{O_2} = \frac{r}{\eta p} \qquad (5)$$

where η is a constant for a particular surface and is a measure of the contribution of the nature of the surface to the probability of spin disorientation due to the presence of oxygen Thus re-writing the equations in terms of line widths

$$\Delta H = \Delta H_O + \eta p/r \qquad (6)$$

where ΔH_O is the line-width in the absence of oxygen. The term η may be further elucidated by the observation that η would appear to be proportional to ΔH_O for a given type of carbon, that is

$$\Delta H = \Delta H_O + \varphi \Delta H_O \frac{p}{r} \qquad (7)$$

Table 1 shows the values of ΔH_O, $\frac{d(\Delta H)}{dp}$ and φ for the range of carbon blacks excluding those with highly oxidized surfaces, that is, the channel blacks It can be seen that in view of the fact that these surfaces are far from identical the agreement for the value of φ is good

Table 1

Trade name	ΔH_O (gauss)	$\frac{d(\Delta H)}{dp}$ (gauss mm $^{-1}$)	$\frac{r}{(A)}$	φ
'Philblack A'	44	0 018	380	0 16
Kosmos 20'	15	0 004	650	0 17
'Kosmos 40'	15	0 004	525	0 14
'Spheron 6' (heat-treated to 400° C)	22	0 014	250	0 16
'Spheron 6' (heat-treated to 800° C)	52	0 032	250	0 15
'Vulcan 6'	40	0 033	230	0 19
'Vulcan 9'	46	0 045	200	0 19
'Shawinigan'	4 9	0 0016	400	0 13

The fact that $\frac{d(\Delta H)}{dp}$ is proportional to ΔH_O would seem to suggest that the spin interaction between oxygen and the spins of the system occurs via the surface imperfections that are responsible for the initial line-width

Table 2 shows the effect of a more highly oxidized surface on the values of $\frac{d(\Delta H)}{dp}$ and φ it can be seen that oxidation considerably increases the value of $\frac{d(\Delta H)}{dp}$ and at the same time produces a considerable variation in the value of φ

Table 2

Trade name	ΔH_O	$\frac{d(\Delta H)}{dp}$	r	φ
'Dixie 77'	4 7	0 028	300	1 7
'Spheron 6'	6 3	0 20	250	8
'Black Pearls 74'	5 0	1 4	170	48
'Black Pearls 2'	5 0	0 65	120	15
'Black Pearls 46'	5 0	0 28	280	16

It would appear that in this case the arguments no longer hold, probably because the free spins are much more likely to be localized in quinnoid structures and to behave more as a surface free radical Alternatively the presence of electron-attracting groups at the surface increases the length of time an unpaired spin is under the influence of the surface and thus effects due to variations between surfaces become magnified

At the same time, of course, the effectiveness of oxygen in broadening the line is increased It is very noticeable that heat treatment at 400° C , which removes much of the chemisorbed oxygen, brings 'Spheron 6' into the framework of the initial scheme (compare Table 1, items 4 and 5, and Table 2, item 2)

Equation (7) is likely to hold, therefore, in all cases of a reasonably pure non-oxidized carbon surface where the surface relaxation is small compared with the bulk relaxation time and where the particle radius is small compared with the skin depth

I thank Prof A Charlesby for his advice

CRYSTALLINE FORMS OF CARBON: A POSSIBLE HEXAGONAL POLYMORPH OF DIAMOND

By SABRI ERGUN and LEROY E. ALEXANDER*

Pittsburgh Coal Research Center, U S Department of the Interior, Pittsburgh

THE number of valence electrons of elements belonging to Group IV in the Periodic Table, that is, carbon, silicon, germanium, tin, etc , or of two elements symmetrically arranged relative to Group IV, for example, AlN, BeO, ZnO, ZnS, etc , in principle permits the formation of a tetrahedral covalent bond between each atom and its four neighbours[1] Regular three-dimensional linking of tetrahedrons yields hexagonal-close-packed layers One of the two simplest forms of hexagonal-close-packed layer structures has a cubic symmetry and yields a diamond-type lattice, and the other yields a hexagonal wurtzite-type lattice

Close-packed layers can be characterized by a particular sequence of layers designated by *A*, *B* *C*, etc , the projections of the atoms in the layers designated by a common letter, for example *A* being identical Tetrahedral bonding yields layers that are alternately spaced by one bond-length and one-third of a bond-length The positions of the atoms in the adjacent layers separated by one bond-length are identical The layers form the (111) planes in the cubic lattice and the (00 2) planes in the hexagonal lattice These two structures differ in the arrangement of the adjacent layers which are separated by one-third bond-length In the cubic structure the sequence can be represented by three pairs, $/A\text{–}A/B\text{–}B/C\text{–}C\diagdown A\text{–}A/$, and in the hexagonal structure by two pairs, $/A\text{–}A/B\text{–}B\diagdown A\text{–}A/$ The positions of the atoms in these two sequences are illustrated in Fig 1.

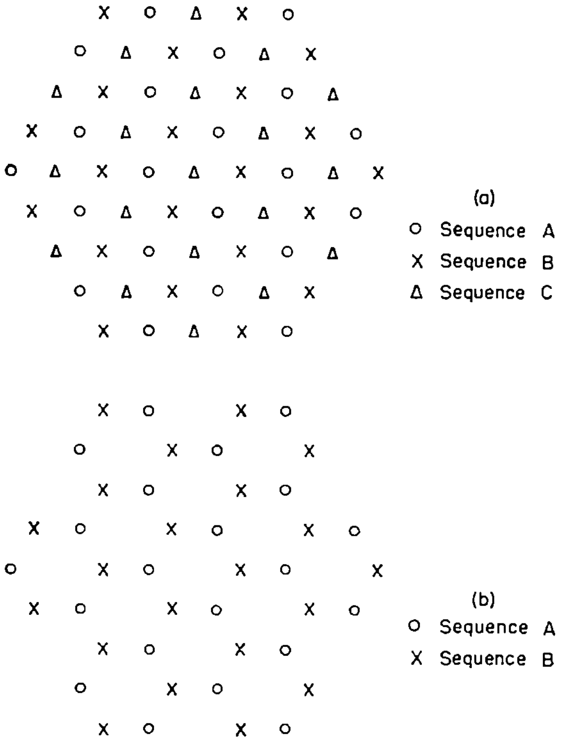

Fig. 1 Projections of atoms on (111) plane of face-centred cubic structure (*a*) and on (00 2) plane of hexagonal structure (*b*)

Reciprocal spacings ($1/d$), line indices (hkl), geometric structure factors (F_g) and relative scattering intensities (I_c) of the two crystalline forms of tetrahedral carbon are given in Table 1 The indices given cover those observable with copper $K\alpha$ radiation It is readily observed that the hexagonal structure, having less symmetry, gives rise to many additional reflexions

Many tetrahedral structures are known to exist both in cubic and hexagonal crystalline forms, and many form a variety of stacking sequences The classic example is ZnS The cubic crystal is known as sphalerite and the hexagonal as wurtzite Mixtures of SiC, ZnS and of many wurtzite-type compounds are known[1,2] The transformation from cubic lattice to hexagonal and vice versa, or the formation of mixed structures, can be accomplished by rotation or by translation of layers In addition to wurtzite-type compounds, other compounds, such as ice, are known to undergo such transformations Ice has the hexagonal crystalline form at ordinary temperatures, below −70° C it has the cubic form[3,4] It is rather remarkable that carbon, silicon and germanium have been reported to exist in face-centred-cubic form only It is of interest to know whether or not carbon can exist in the hexagonal arrangement under some conditions It should be pointed out that for a number of years graphite was believed to exist only in a hexagonal crystalline form having an *–A–B–A–B–* sequence Later work, however, indicated that the *–A–B–C–A–B–C–* sequence of stacking (rhombohedral graphite[5,6]) and/or other sequences[7] existed in graphites

It appears that the hexagonal form may exist in diamonds, causing what are termed layer faults and growth faults Recently it was shown that peak shifts and line broadenings observed in X-ray diffraction patterns of diamonds could be explained by altering the sequence of nearest layer pairs[8] That peak shifts and line broadenings would likewise be observed if diamonds contained some hexagonal layer sequences is also evident from an inspection of Table 1 The (10 0) and (10 1) reflexions of the hexagonal lattice would broaden and produce peak shifts of the (111) reflexions of the face-centred cubic lattice Similarly the (20 0) and (20 1) reflexions would influence the (113) reflexions, the (20 3) and (21 1) reflexions would influence the (133) reflexions, etc For every face-centred cubic reflexion shown in Table 1 there is a corresponding (that is, having the same d-spacing) reflexion of the hexagonal lattice (with the exception of the (400)), and each one is closely accompanied by additional reflexions

In both the cubic and hexagonal structures the closest layer pairs, that is, *A*/*B*, *B*/*C*, etc, form buckled hexagonal rings which are of chair type The buckled rings would project on the eight octahedral faces $\{111\}$ of a face-centred cubic crystal, every face having one parallel to it The normals to these face pairs are parallel to the four vectors connecting any one atom to its four neighbours In the hexagonal structure atoms form chair-type buckled rings on only the two faces that form the basal planes, namely, (00 2) and (00 $\bar{2}$) On the other three face pairs, denoted in the hexagonal model by (10 0) and ($\bar{1}$0 0), (1$\bar{1}$ 0) and ($\bar{1}$1 0), and (0$\bar{1}$ 0) and (01 0), boat-type rings are formed Since boat-type rings cannot be stacked on chair-type rings by normal tetrahedral bonding, mixed structures are possible only as a result of stacking variations along one axis, namely, the c-axis of the hexagonal lattice If hexagonal structures could be made to grow on the eight octahedral faces $\{111\}$ of a face-centred cubic crystal, a continuous and homogeneous crystal would not be formed Growth on two adjacent faces cannot be joined by tetrahedral bonding This is easily seen if one attempts to attach a few models of the hexagonal unit cell on a model of the face-centred cubic unit cell This limited miscibility of these two crystalline forms could result in growth faults in the formation of diamonds

†The $I_c = m\,|F_g|^2$

Of particular interest are the so-called amorphous carbons. Recent studies indicated that X-ray scattering intensities of non-graphitizable carbons could be explained by the presence of tetrahedral as well as trigonal and π structures[9]. Their non-graphitizability, hardness and sometimes density[10] favour the tetrahedral form. If under the conditions of carbonization, probabilities of formation of the cubic and hexagonal structures are not prohibitive in favour of one or the other, a skeletal network of interpenetrating crystallites would be formed; the closer the probabilities, the smaller the crystallites. Such a system could be termed polytype-crystalline in contra-distinction to the term polycrystalline, which is used to describe a solid composed of many crystals (or crystallites) of varying sizes but of the same type. Of course, the probabilities of formation of trigonal and π structures should not be overlooked. If tetrahedral and trigonal and π bonds are formed during the pyrolysis of carbonaceous materials, the resulting structures would be extremely complicated. Whether diamonds, graphites or polytype carbons are formed would depend upon the reaction time and the relative probabilities of formation of various crystalline forms, the probabilities being dependent upon the conditions under which the reaction takes place. It is interesting to note that under proper conditions of pyrolysis some carbon-containing materials can be carbonized to yield what are known as pyrolytic carbons in which the graphitic layers formed attain sizes of several thousand angstroms[11], where pyrolysis of polyvinylidene chloride[12] and of coals[13] yields crystallites of a few angstroms in size, that is 6–15 Å. Polytype crystallinity appears to offer a very reasonable explanation for the differences. Therefore, various crystalline forms of carbon should be considered in analysing the structure of the so-called amorphous carbons.

MEASUREMENT OF CURRENTS BELOW THE SURFACE AT A LOCATION IN THE WESTERN EQUATORIAL ATLANTIC

By T. E. POCHAPSKY

Columbia University, Hudson Laboratories, Dobbs Ferry, New York

IN a communication to *Nature*, A. D. Voorhis[1] presented evidence for a strong eastward moving current just below the surface of the Atlantic in the eastern equatorial region from 10° W. to at least 20° W. We have recently completed some measurements at a fixed location on the western side of the Atlantic, and these revealed easterly currents which are weaker than those reported by Voorhis but which occur not only just under the surface but also at great depths. Voorhis found a long, narrow stream moving at a velocity near 100 cm sec^{-1} at a depth of 105 m. At our location, 2° 05.5′ N. and 35° 00.0′ W., we found an easterly current of 18 cm sec^{-1} at a depth of 91 m. The surface current was to the west and amounted to about 25 cm sec^{-1}. Rather than explore to find whether we were at the edge of a strong stream, we chose to examine how the current changed with depth. Measurements were made by following neutrally buoyant floats and were necessarily limited to a relatively small number of levels. At a depth of 130 m, the current was northerly at 3 cm sec^{-1} and shifted to southerly near 450 m. The current jumped to 24 cm sec^{-1} in an easterly direction at the 1,100-m level and continued in that direction at 12 cm sec^{-1} when the depth was 1,530 m. Below a depth of 2,000 m, the currents were weaker and to the north.

The entire series of measurements is summarized in Table 1.

Our knowledge of the flow below the surface in the equatorial Atlantic is theoretical and leans heavily on the work of Defant[2] and Wust[3]. Even so, their results are not completely applicable at the equator because the Coriolis force is small there and because their data emphasize meridional flows. Defant surmises the existence of a practically motionless layer of water below the surface. At our location, this would be 750 m down. An easterly countercurrent could exist in the top few hundred metres, and Neumann[4] has shown how the trade winds can produce a westerly surface current over such a countercurrent so as to produce a situation resembling that observed in our measurements.

Defant's analysis shows currents which are usually smaller than 3 cm sec^{-1} beneath the moving surface waters down to a depth of approximately 1,500 m. Continuing the study down to the bottom, Wust found two strong streams. One of these carries North Atlantic Deep Water southward at speeds approaching 15 cm sec^{-1} while hugging the continental slope off South America. The other stream is displaced 200–300 km to the east of this and moves Antarctic Bottom Water to the north at speeds up to 12 cm sec^{-1}. Our location should have been nearly over this latter stream. The measurements from 1,950 m down to 3,240 m revealed a northward current of approximately 5 cm sec^{-1}, which is consistent with Wust's results. On the other hand, the large zonal flows found at intermediate depths are unexpected.

By tracking neutrally buoyant, that is, Swallow-type[5], floats, it is possible to obtain velocities averaged over a long time, and tidal or other brief fluctuations in the measurements can be avoided. Our floats[6] telemetered their depths with an accuracy of a fraction of 1 per cent and have transponding features which allowed us to determine their positions relative to the ship with high accuracy. Determination of the position of the ship was made by dead reckoning

* The numbers in parentheses are the sets of the ship They varied in the same fashion whether there was wind or not, excluding occasional small squalls

† This direction is accurate to ± 10°

‡ Two floats were dropped at the same time 'Rel' refers to measurements obtained by adding the relative vector distance between the floats to the position of the sister float

with respect to a buoyant float secured to the ocean floor by a mile length of cord This transponder float was 1,200 fathoms below the surface On occasion, the skies cleared so that we could locate the transponder by means of a star fix The origin of the track of a free float was known to an accuracy of ± ½ mile, and the final position was known to approximately ± 1 mile

The velocities reported in Table 1 were obtained by dividing the vector distance a free float moved by the total time at depth A float did not move with a constant velocity over its course, and the path itself tended to curve to the right Our precision of measurement did not allow investigating these features when the current was large The deeper floats remained near the anchored transponder, and it was apparent that they meandered in the quadrant northwest of the transponder One such float followed a clockwise path and passed near its initial position after 31 h Another one had a more nearly random counter-clockwise motion These trends in the movements were real, but details were obscured by errors in tracking Although measurements can be made to an accuracy of ± ½ mile relative to the transponder, it is possible that bottom currents could swing the transponder itself over this range We can, however, look on the results for the deep floats as reasonable approximations to the average velocities over periods of a day or so

MEASUREMENT OF PARTICLES

By Dr C. N. DAVIES

(Medical Research Council), London School of Hygiene and Tropical Medicine, London, W C I

IRREGULAR particles, seen as silhouettes, can be measured in various ways What is meant by the terms radius, diameter, size, is frequently unspecified, and figures derived from such measurements are seldom related to the statistics of shape and then only by factors of doubtful meaning

Any of the common methods of expressing the sizes of the particles in a preparation can, however, be associated with the average of a series of analogous measurements of a single particle, oriented in different ways, this average has an exact geometrical significance

It is suggested, therefore, that if the repetition of the measurements be made not at random on a single particle, but once per particle over a number of particles lying randomly, then their average will have the same geometrical significance for the group as the average of the measurements taken on a single particle has for that individual

The validity of this proposition is obvious if the particles are all the same and favour all orientations equally The former restriction is rarely satisfied and the latter is notoriously untrue for orientation in three dimensions[1] Its validity can easily be tested, in any particular instance, by measuring a quantity S over a number of particles, 1, 2, 3, n and repeating the measurements in different directions, α, β, γ, . . . ν spread evenly over an azimuth of 180° The measurements comprise the array

$$\begin{array}{cccc} S_{1\alpha} & S_{2\alpha} & S_{3\alpha} & & S_{n\alpha} \\ S_{1\beta} & S_{2\beta} & S_{3\beta} & & S_{n\beta} \\ S_{1\gamma} & S_{2\gamma} & S_{3\gamma} & & S_{n\gamma} \\ \\ S_{1\nu} & S_{2\nu} & S_{3\nu} & & S_{n\nu} \end{array}$$

If the averages of each row are identical, within an acceptable margin, they must match the mean of the averages of the columns, this proves the truth of the proposition for the material and technique of preparation in question This result will be referred to as group extension of the average

A popular measurement is that of the projected area diameter, D In this the problem of shape is evaded by requiring the observer to condense the outline of the particle into a circle of the same area (Fig 1) The measurement is usually made subjectively, it can be done with precision, either quickly, by light extinction, or slowly with a planimeter

Another measurement is the distance between parallel tangents to each particle (Fig 2) The average over a number of particles, all tangents being parallel, is known as Feret's statistical diameter, $\overline{F}$ (ref 2)

The distances, F, between pairs of parallel tangents to a single particle can be measured in different directions The distance between any pair is the sum of the projections of the elements, p_i, of either of the two parts of the perimeter between the points of contact of the tangents, provided that the perimeter is nowhere concave Concavities result in over-

Fig 2 Distance between parallel tangents F

Fig 3 Perimeter, P, of a particle which is not convex

Fig 4 Projection of elements of perimeter

Fig 5 Area is $F_i c_i$

Fig 6 Method of obtaining the true perimeter Note that the reflexion of the part of the outline which is inside the tangent bridging the convexity still leaves re-entrant regions Further reflexions are necessary until a convex outline results

Fig 7 Segments of a diameter through O

Fig 8 Re-entrant outlines *a*, Equation (4) is valid if O is in the hatched area, *b*, the entire area is swept by tangents to the outline and equation (4) does not hold

lapping of the projections of the elements, p_i, in some directions of projection The elements project additively only for convex outlines, an outline with concavities projects as a string drawn tightly round it (Fig 3)

When F is averaged over all possible directions of projection each element of projection is similarly averaged (Fig 4) and

$$2\bar{F} = \Sigma \frac{2}{\pi}\int_0^{\pi/2} p_i \cos\theta \, d\theta = \Sigma \frac{2}{\pi} p_i$$

$$\text{Hence} \quad \bar{F} = \frac{P}{\pi} \text{ for one particle} \qquad (1)$$

where P is the perimeter of the particle, if convex, or the length of a string drawn tightly round it if not convex[3]

Subject to group extension of the average being valid, the Feret statistical diameter of a number of particles is their average perimeter divided by π (ref 4)

It is obvious that the area, A, of a particle is given by the distance F_i between any pair of parallel tangents multiplied by the mean length c_i of chords parallel to the tangents (Fig 5)

Hence, for orientation i

$$A = F_i c_i \qquad (2)$$

Since c_i is weighted according to the length, F_i, the mean of c_i over all orientations is the mean length, $\bar{c}$, of a large number of chords drawn at random through the outline of the particle, hence

$$\bar{c} = \frac{\Sigma F_i c_i}{\Sigma F_i}$$

which, by (1) and (2), gives

$$\bar{c} = \pi A/P \qquad (3)$$

This result was obtained by Crofton[5], who also showed that

$$\overline{c^3} = 3A^2/P \qquad (4)$$

By group extension of the average the mean of single chords measured on a number of particles at random gives π times the mean of the ratio of their area to perimeter, P, defined here and there is an analogous extension of (4)

The effect of a particle having a re-entrant outline is to make the perimeter as estimated by equation (1) too short The correct perimeter is easily obtained by reflecting the concavity about the tangent to the outline which encloses it and measuring the chords for Feret's diameter to the reflected extension instead of to the tangent (Fig 6) The area of re-entrant particles can be correctly obtained from equations (2) and (3) by measuring the two or more parts of each chord which cuts a particle more than once and adding them together

If the lengths of the chords drawn at random are

$$c_1, c_2, \quad c_n$$

where

$$c_1 = \bar{c} + \delta_1, \text{ etc}, \text{ and } \Sigma\delta = 0$$

then

$$n\overline{c^2} = n\bar{c}^2 + \Sigma\delta^2$$

and

$$n\overline{c^3} = n\bar{c}^3 + 3\bar{c}(n\overline{c^2} - n\bar{c}^2) + \Sigma\delta^3$$

Hence, using (3) and (4)

$$A = \pi(\overline{c^2} - \frac{2}{3}\bar{c}^2) + \frac{\pi}{3n\bar{c}}\Sigma\delta^3 \qquad (5)$$

This enables the area of a shape to be computed from the lengths of random chords with group extension to the mean area of a number of particles

The last term in equation (5) is related to the third moment of the distribution of chord-lengths, that is to the skewness of their distribution; the term is usually small, being only a 2½ per cent correction for circles

Instead of drawing chords at random suppose they are all drawn through one point, O, inside the outline of a particle Let d be the length of a chord and suppose O divides it into segments r_1, r_2 (Fig 7) so that $d = r_1 + r_2$ If the chord rotates about O through an angle π it sweeps out the area and

$$\begin{aligned} A &= \int_0^\pi \tfrac{1}{2} r_1^2 d\theta + \int_0^\pi \tfrac{1}{2} r_2^2 d\theta \\ &= \frac{\pi}{2} (\overline{r_1^2} + \overline{r_2^2}) \\ &= \frac{\pi}{2} \overline{d^2} - \pi \overline{r_1 r_2} \\ &= \frac{\pi}{2} \overline{d^2} - \pi\rho \sqrt{\overline{r_1^2}\,\overline{r_2^2}} \end{aligned} \tag{6}$$

where ρ is the coefficient of correlation between r_1 and r_2

$$\rho = \overline{r_1 r_2} \Big/ \sqrt{\overline{r_1^2}\,\overline{r_2^2}} \tag{7}$$

This result is valid for all convex and some re-entrant outlines, subject to O not being on any tangent to the outline (Fig 8)

If O is a point on the periphery

$$A = \frac{\pi}{2} \overline{d_p^2} \tag{8}$$

where d_p is a diameter through a point on the periphery

This result is independent of the location of O on the periphery so long as it is not at a discontinuity

The correlation between r_1 and r_2 depends on the position of O within the outline, presumably the correlation will be greatest for a given outline when O is the centroid In this case

$$\overline{r_1^2} = \overline{r_2^2} = \overline{r^2} = A/\pi$$

Hence, from (5)

$$A = \frac{\pi}{2(1 + \rho)} \overline{d_c^2} \tag{9}$$

where d_c is a diameter through the centroid Notice that $\overline{d_c^2} = (1 + \rho)\overline{d_p^2}$

As before, this result extends to give the mean area of a number of particles from the mean square of the length of a chord through the centroid of each particle The mean of chords through the centroids of a group of particles is known as Martin's diameter[6]

The value of the correlation coefficient of the segments r_1, r_2 of a chord through the centroid of a figure depends on its symmetry It is unity for a figure having two perpendicular axes about which it is either symmetrical or skew symmetrical Thus $\rho = 1$ for circle, ellipse, rectangle and parallelogram The correlation coefficient has been calculated for three triangles with the following results

Triangle	ρ	$\delta A/A$ (per cent)
Isosceles, 20° at vertex	0.95	2½
Isosceles, 160° at vertex	0.97	1½
Equilateral	0.928	4

It is possible that the smallest value which ρ can take is that for an equilateral triangle, though this has not been proved The last column shows the error

$$\frac{\delta A}{A} = \frac{1 - \rho}{2}$$

which results from computing equation (9) with $\rho = 1$ instead of the true value, this gives too small an area

This method of finding the area of irregular shapes might be subject to less personal error than the usual one, based on projected area diameter, because it is probably easier to place a line through the centroid of an outline than to compress it to a circle having the same area, the two methods should be used to check one another, a further independent check is obtainable by measuring chords at random and applying equation (5)

A SINGLY TERMINATED FREQUENCY FUNCTION WITH THREE PARAMETERS

By R ASH and E O POWELL

Microbiological Research Establishment, Porton Down, Salisbury

THE number of singly terminated continuous distributions which are applied to graduating biological data is rather few considering the great variety of such data Apart from the Pearson Type VI distribution with its limiting cases Types III and V and the negative exponential, only the 'lognormal' or Galton–McAlister[1] is in widespread use The lognormal distribution, because of its convenient sampling properties, is often applied without much regard for its suitability, and even when considered hypothesis would suggest a different form[2-4]

Apart from problems of statistical estimation, the lognormal distribution is not algebraically convenient (for example, its characteristic function is not expressible in a simple form) and the same is true of the Type VI in certain kinds of application The distribution to which we wish to direct attention is

$$dF = \frac{x^{\nu-1} \exp\left\{ -\frac{\alpha}{2}\left(\frac{x}{m} + \frac{m}{x}\right)\right\} dx}{2m^\nu K_\nu(\alpha)} \tag{1}$$

where $K_\nu(\alpha)$ is the modified Bessel function of the second kind It is singly terminated below at the origin, it is flexible because, like the Type VI, it has three disposable parameters, and it is fairly easy to manipulate It also lends itself to the elaboration of

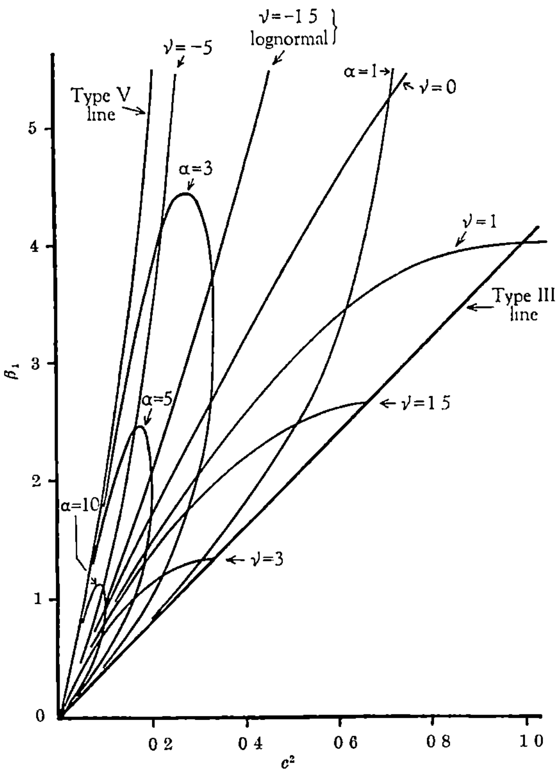

Fig 1 Frequency function of equation (1) Relation between squared coefficient of variation, c^2, and skewness, β_1, for various values of the parameters α, ν

compound distributions It arises naturally in discussing the distribution of the generation times of bacteria The generation time distribution can often be represented by a Pearson Type V, and when this is so, the 'carrier' distribution[5] takes the form (1) If the generation time distribution has the form (1), the carrier distribution is of the same form

The moments μ'_r of (1) about the origin are easily found by writing $x = me^{\theta}$ and using a standard integral for the Bessel function

$$K_\nu(\alpha) = \int_0^\infty e^{-\alpha\cosh\theta}\cosh\nu\theta \, d\theta \, ,$$

we find

$$\mu'_r = m^r \frac{K_{\nu+r}(\alpha)}{K_\nu(\alpha)} \tag{2}$$

The maximum likelihood equations for fitting (1) to a set of data can also be found by the usual procedure maximum likelihood estimates $\hat{m}$, $\hat{\alpha}$, $\hat{\nu}$, of the parameters are given by

$$A = \hat{m}\, K_{\hat{\nu}+1}(\hat{\alpha})/K_{\hat{\nu}}(\hat{\alpha}) \tag{3}$$

$$H = \hat{m}\, K_{\hat{\nu}}(\hat{\alpha})/K_{\hat{\nu}-1}(\hat{\alpha}) \tag{4}$$

$$G = \hat{m} \exp\{\mathscr{K}_{\hat{\nu}}(\hat{\alpha})\}$$

where A, H, G are respectively the arithmetic, harmonic and geometric sample means, and $\mathscr{K}_r(\alpha)$ has been written for

$$\frac{\partial}{\partial\nu}\left\{\log K_\nu(\alpha)\right\}$$

If in (1) α and m are allowed to tend to zero in such a way that α/m tends to a finite limit, say $2/\beta$, and if at the same time ν is positive, the limiting form reached is the Pearson Type III

$$\frac{x^{\nu-1}\exp(-x/\beta)}{\beta^\nu\,\Gamma(\nu)}$$

since near $\alpha = 0$, $K_\nu(\alpha)$ is about $\alpha^{-\nu}2^{\nu-1}\Gamma(\nu)$ Similarly the Pearson Type V is reached by making $\alpha \rightarrow 0$, $m \rightarrow \infty$ with αm finite and ν negative In fact the representative points of (1) in the Pearsonian β_1, β_2 diagram (see, for example, Pearson[6]) occupy the same region as those of the Type VI distribution The Type VI with lower terminus at the origin also has the same range of coefficient of variation and of skewness Fig 1 shows how the squared coefficient of variation, c^2, and skewness, β_1, are related to the parameters α and ν (m does not enter since it affects only the scale) Such a diagram can be used to obtain from the sample moments rough estimates of α and ν with which to begin an iteration to find $\hat{\alpha}$ and $\hat{\nu}$

(It is worth noting at this point that when the terminus of a distribution such as (1) is naturally fixed, the coefficient of variation acquires an intrinsic significance which it does not otherwise possess If the moments of a distribution are to be used to suggest a suitable functional form, it is better to infer the form from the coefficient of variation and skewness rather than the skewness and kurtosis—when this can be done—because of the relatively larger sampling variance of the fourth moment)

Since neither the moment nor the maximum likelihood equations can (in general) be solved explicitly for the parameters, the application of (1) demands the use of comprehensive and convenient tables of the Bessel function and its derivative with respect to the order Suitable tables do not yet exist, but Dr H J Gawlik, of the Royal Armament Research and Development Establishment, Fort Halstead, Kent, is undertaking their preparation

When ν can be assigned in advance and is a fixed integer n, or of the form $(2n + 1)/2$, and n is not too large, existing tables can be used There are several cases of fixed ν which give rise to distributions of special interest, thus $\nu = 1$ gives Keynes's[7] distribution Another particular case, that of $\nu = -3/2$, is immediately manageable and is remarkable as a very close approximation to the lognormal distribution

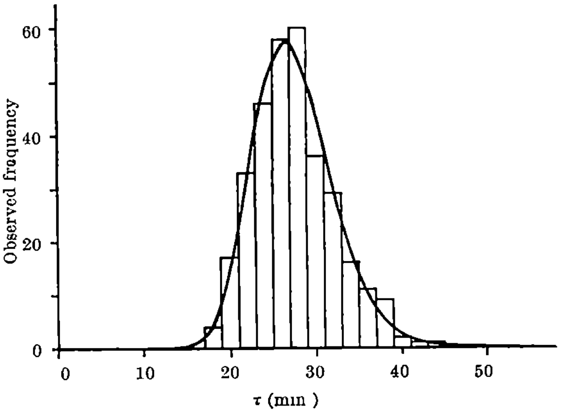

Fig 2 Generation time (τ) distribution of *Aerobacter aerogenes* with a fitted curve of the form of equation (1), $\nu = -3/2$

We have, since $K_{-\nu}(\alpha) \equiv K_{\nu}(\alpha)$,

$$K_{-1/2}(\alpha) = (\pi/2\alpha)^{1/2} e^{-\alpha}$$

$$K_{-3/2}(\alpha) = K_{-1/2}(\alpha)\,\{1 + 1/\alpha\}$$

$$K_{-5/2}(\alpha) = K_{-1/2}(\alpha)\,\{1 + 3/\alpha + 3/\alpha^2\}$$

and so from (3) and (4)

$$A/H = (\hat{\alpha}^2 + 3\hat{\alpha} + 3)/(\hat{\alpha} + 1)^2$$

$$A = \hat{m}\,\hat{\alpha}/(\hat{\alpha} + 1)$$

Also, from (2)

$$c^2 = 1/\alpha\,,\ \beta_1 = (1/\alpha + 3)^2/\alpha$$

Thus $\beta_1 = c^2\,(c^2 + 3)^2$ Now this relation between the skewness and coefficient of variation applies also to the lognormal distribution[8], if a distribution of the form (1) with $\nu = -3/2$ and a lognormal distribution have their first two moments equal, their third moments will also be equal On the c^2, β_1 diagram (Fig 1), the lognormal distribution is represented by the same line as (1) with $\nu = -3/2$ For the graduation of data, therefore, the two distributions will often be interchangeable

Example Observations of the generation time distribution of *Aerobacter aerogenes* growing on a synthetic medium at 35° (ref 9)

Distribution (1) with $\nu = -3/2$ and also a lognormal distribution were fitted by the method of maximum likelihood The sample statistics were

No of observations	323
Mean	27 511
Variance	21 965
3rd moment	54 912
4th moment	1544 418
Harmonic mean	26 742
Coefficient of variation	0 169
Skewness, β_1,	0 298
Natural logarithm of geometric mean, G	3 30035
Variance of logarithm of G	0 0285077
Estimates of parameters $\hat{\alpha}$ =	34 75
$\hat{m}$ =	28 30

(Unit of time 1 min)

The fitted curve of (1) is shown superposed on the histogram of the observations in Fig 2 (By the χ^2 test, the fit is good $\chi^2 = 3\ 6$, 8 degrees of freedom) The fitted lognormal curve is indistinguishable from it on the scale of the diagram

ENZYMATIC REACTION SEQUENCES AND CYTOLOGICAL DIMENSIONS

By PAUL B WEISZ

Socony Mobil Oil Co Inc , Research Department, Paulsboro Laboratory, Paulsboro, New Jersey

OCCURRENCE of a number of sequential reaction steps catalysed by various enzyme systems is a characteristic of biochemical conversion processes Such polystep catalytic reaction sequences have been studied and experimentally demonstrated in hydrocarbon reaction systems It has been demonstrated[1-4] that, in a sequential reaction occurring on different catalyst entities, the physics of the transport process of the intermediates leads to a relationship between the attainable rate of the overall reaction, the thermodynamic properties of the intermediate, and the dimensions of the physical system

The trend of results of cytochemical investigation is the finding of considerable localization of certain enzymatic agents within specific parts of the cell[5]. It is therefore of interest that the aforementioned relationships should analogously apply to an enzyme system They should give us information concerning separation of participating components within such enzymatic apparatus, and therefore should also define a maximum feasible biological cell size

The Model and Critical Relationships

A simple first-order treatment of a sequential reaction step

$$A_{i-1} \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} A_i \xrightarrow{k_2} A_{i+1} \qquad (1)$$

leads to the reaction-rate

$$\mathrm{d}N/\mathrm{d}t = [A_{i-1}]\,k''\,,\ k'' = k_2\,[1/K + k_2/k_1]^{-1} \qquad (2)$$

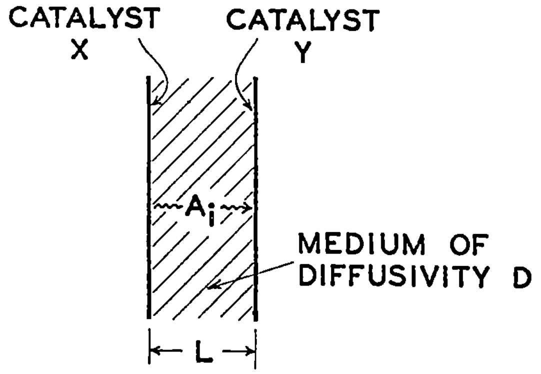

Fig 1 Reaction $A_{i-1} \overset{\text{at } X}{\rightleftarrows} A_i \overset{\text{at } Y}{\longrightarrow} A_{i+1}$

wherein $K = k_1/k_1' = [A_{i,\mathrm{eq}}]/[A_{i-1}]$ is the equilibrium constant characteristic of the formation of the intermediate A_i This rate is seen to be unlimited in magnitude provided the rate constants k_1 and k_2 are large enough, regardless of how unfavourable the $A_{i-1} \rightarrow A_i$ might be thermodynamically Now let us physically separate the sites on which $A_{i-1} \rightarrow A_i$ is catalysed (sites X) from those catalysing $A_i \rightarrow A_{i+1}$ (sites Y) (Fig 1) Here the concentration of the A_i species at X, $[A_i]_X$, will generally not be equal to that of $[A_i]_Y$ at the surface Y Instead, the two will be related to the overall reaction-rate through the diffusion equation

$$(\mathrm{d}N/\mathrm{d}t)_s = \frac{D}{L}\,([A_i]_X - [A_i]_Y) \qquad (3)$$

wherein $(\mathrm{d}N/\mathrm{d}t)_s$ is the overall rate of reaction per unit surface area, since in the steady state the rate of reaction for each sequential step has to equal the overall rate. When this is taken into account[5] in the kinetic derivation we obtain, for the rate of the system

$$(\mathrm{d}N/\mathrm{d}t)_s = [A_{i-1}]\,k''\,(1 + k''\,L/KD)^{-1} \qquad (4)$$

in place of equation (2). D is the diffusion constant for intermediate molecules A_i in the medium between X and Y, and L is the characteristic distance of separation between X and Y. With $k'' \rightarrow \infty$ the rate is seen to go to an absolute ceiling value of

$$(\mathrm{d}N/\mathrm{d}t)_{s,\ \max} = [A_{i,\mathrm{eq}}]D/L \qquad (5)$$

A volume element contains $1/L$ surface elements, so that the maximum possible rate per unit volume will be

$$(\mathrm{d}N/\mathrm{d}t) \leq [A_{i,\mathrm{eq}}]D/L^2 \qquad (6)$$

Thus we have a relationship between the velocity of the overall rate process, $\mathrm{d}N/\mathrm{d}t$, a thermodynamic characteristic $[A_{i,\mathrm{eq}}]$ of a reaction step and the physical properties of the multiple catalyst system, namely, the characteristic distance L between catalytic surfaces and D, the diffusion co-efficient in the intervening medium.

In previous work[4,5] it was shown that a diffusion criterion of the same form arises in a multiple catalyst system of quite another type, as regards the geometry of the model: catalytic sites are distributed throughout finite volumina of space, some of them contain only catalyst X, others only catalyst Y, as pictured by the model in Fig. 2. In this case again, equation (5) defines conditions for negligible diffusion inhibition, that is, for adequate utilization of the available catalysts.

It is well known[6] that the magnitude of calculated diffusion effects is not highly sensitive to the exact geometry of a system so that in any event L can be considered to be a typical length parameter. We may therefore examine the implications of equation (6) for systems where, for example, two different enzymatic materials are separated by a magnitude L across the cytoplasm of a cell, or by a membrane (for example, the mitochondrial membrane) of thickness L, or where one enzyme system may be distributed diffusely over a volume such as a mitochondrion, nucleus, etc., of characteristic size L, and another enzyme is available in the surrounding cytoplasm, and many similar situations.

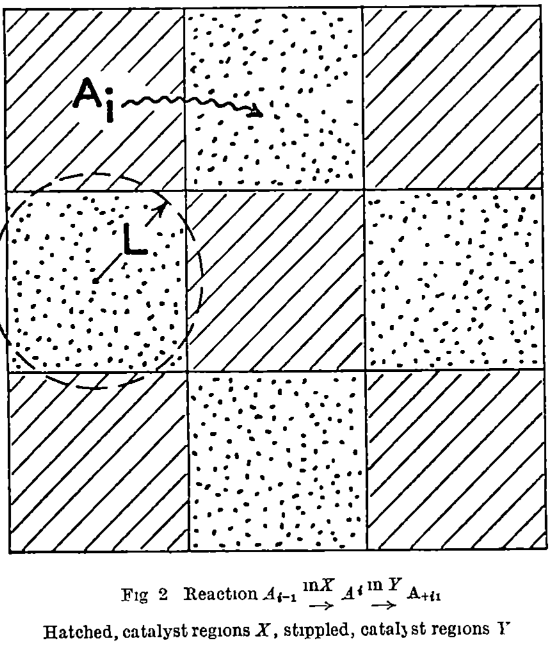

Fig. 2. Reaction $A_{i-1} \xrightarrow{\text{in } X} A_i \xrightarrow{\text{in } Y} A_{i+1}$

Hatched, catalyst regions X; stippled, catalyst regions Y

Cytological Implications

In a reaction sequence of several steps, the condition (6) must be satisfied by each intermediate $[A_i]$. If a number of steps is accomplished by intermediates 'shuttling' back and forth between the same pair of catalytic areas, that is, through the same distance dimension L, then, if for the intermediate existing at the lowest concentration the inequality (6) is satisfied, all other reaction steps will also proceed without difficulty. If various reaction steps are catalysed by various pairs of catalytic areas located at different characteristic distances, then conditions (6) must be satisfied for each pair individually. If we know the concentration of an intermediate involved in a reaction sequence proceeding at a given rate, then (6) will give us a maximum dimension of the apparatus which includes both enzymatic systems involved in its production and conversion.

Cell size. We might now estimate for the processes of cell metabolism the maximum dimension L, that is, a maximum allowable cell size, from the magnitudes of the reaction-rate $\mathrm{d}N/\mathrm{d}t$, and the concentration of the intermediate species $A_{i,\mathrm{eq}}$. We will assume that the actual concentration does approach the attainable equilibrium concentration, that is, that the enzyme catalyst has developed to fairly optimum activity. We may expect the diffusivity to be a magnitude typical for large molecular species in an aqueous medium, that is, $D \approx 10^{-6}$ cm ^{2}/sec.

The metabolic rate of oxygen uptake by various organs, cells, bacteria is of magnitude 10^{-2} c.c. oxygen/min./gm., or $\frac{\mathrm{d}N}{\mathrm{d}t} \sim 10^{-8}$ moles/sec. cm ^{3}. Let us take this as a typical rate magnitude.

We find the following dimensions L for various concentrations of reaction intermediates:

$[A_i]$ $\frac{\text{moles}}{\text{cm}^3}$	10^{-12}	10^{-10}	10^{-8}	10^{-6}	10^{-4}	10^{-2}
L cm	10^{-5}	10^{-4}	10^{-3}	10^{-2}	10^{-1}	1

Now, what are typical magnitudes for the concentration of intermediate reacting species in oxygen metabolism? Cell respiration is seriously inhibited by 0.5×10^{-8} moles/c.c. of a poisonous ion, such as cyanide, indicating that some important species exist at a concentration as low as this (see, for example, ref. 7). Furthermore, the concentration of cytochrome c in yeast cells is also found to be of magnitude 10^{-8} moles/c.c. With this magnitude, and assuming that the concentration of an enzyme specific for a given reaction will not greatly exceed in magnitude the concentration of the species to be reacted, we obtain for the maximum allowable dimension

$$L \sim 10^{-3} \text{ cm}$$

which is indeed of the order of actual cell dimensions, that is, from about 5×10^{-4} to 5×10^{-3} cm.

Equation (6) contains the quotient $\frac{dN}{dt}\frac{1}{[A_{i,eq}]}$ This allows us to use figures for reaction-rate of unit volume of matter (such as tissue) although the material may include not only the enzymatic apparatus but also other material which does not participate in the reaction, since the measured concentration is based on the same total volume It is interesting to note, therefore, that measured concentrations among samples may vary by orders of magnitude, but the same critical dimension for the specific enzymatic apparatus will be indicated by an approximately constant ratio of rate-to-concentration An example for this, applicable to oxygen metabolism and cytochrome *c*, is contained in the measurements of Pappenheimer and Hendee[8] for various rat tissues from whose data we have drawn Fig 3

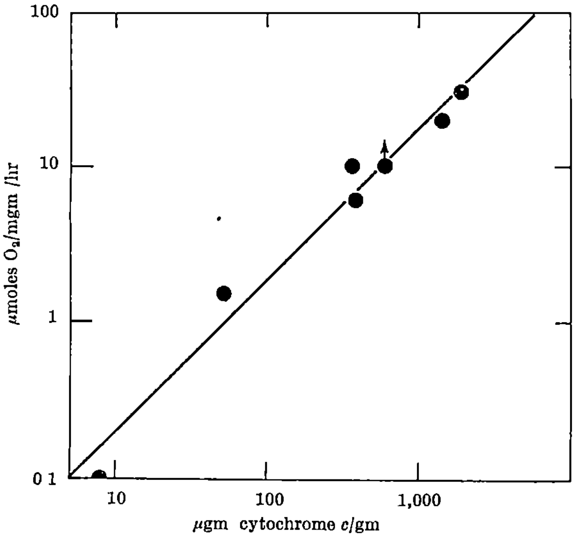

Fig 3

This finding, critically interpreted, establishes only a maximum possible dimension, not necessarily the actual dimension However, the consistent finding of the same order of magnitude rather than a range of magnitudes would strongly suggest that such dimension is in fact involved in the process

This example calculation here also demonstrates that reaction intermediates occurring at lower concentration than 10^{-8} moles/cm ^{3}, and participating in the same overall rate of metabolism, must be processed by catalytic agents physically removed from each other by distances smaller than the cell dimensions, namely, smaller by at least the square root of the concentration ratio

Turnover numbers and dimension of enzymatic apparatus It is difficult to find many specific instances with quantitative information concerning the concentration of intermediates However, the quotient $\frac{dN}{dt}\frac{1}{[A_{i,eq}]}$ can be transformed to the 'turnover number', T

$$T = \frac{60}{n}\frac{dN}{dt}\frac{1}{[A_{i,eq}]},$$

$$n = \frac{\text{molar enzyme concentration}}{\text{molar reactant concentration}}$$

From this and (6) it follows that

$$L \leqq \left(60 \frac{D}{nT}\right)^{1/2}$$

for the maximal distance magnitudes, or, with $D \sim 10^{-6}$ cm ^{2}/sec and n of order of magnitude unity, we have

$$L \leqq 8 \times 10^{-3}/\sqrt{T} \qquad (7)$$

For enzyme reactions characterized by turnover numbers of 10^2 to 10^6, we obtain

$$L \leqq 10^{-3} \qquad 10^{-5} \text{ cm}$$

The maximal value is again typical of actual cellular dimensions, while processes having very high turnover numbers require greater proximity Thus for processes having turnover numbers of the order of 10^6, the maximum characteristic dimension for the participating enzymatic apparatus approaches a value < 1000 Å , that is, a dimension smaller than the entire mitochondrion (See, for example, the active enzymatic regions identified, by electron microscopic methods[9], on the cristæ mitochondriales)

PRESENCE OF SELENIUM-75 IN LIPOPROTEINS

By DR K P. McCONNELL and DR R S. LEVY
Radioisotope Service, Veterans Administration Hospital, and Department of Biochemistry,
University of Louisville School of Medicine, Louisville

IT has been shown[1] that selenium is as effective as vitamin E in preventing dietary liver necrosis in the rat, multiple necrotic degeneration in the mouse, and exudative diathesis in the chick Since 74 per cent of the serum vitamin E is carried by the serum lipoproteins in the human being[2], it would appear to be of interest to determine if selenium is carried by the serum lipoproteins In the first investigations[3] it was shown that in serum proteins from dogs injected 24 h earlier with selenium-75 and separated

† Protein-bound selenium by the trichloroacetic acid method

by paper electrophoresis, 60 per cent of the paper's radioactivity was equally distributed between the α-2 and β-1 globulins An additional 10 per cent was found in the albumin, β-2 and γ-globulin fractions In later time-distribution investigations[4] selenium was shown to be bound principally to albumin during the first hour, then later transferred and principally bound to specific globulin fractions, namely, α-2 and β-1 Since blood lipids are chiefly associated with the α- and β-globulin fractions, experiments were carried out on a series of dogs and rats in order to determine whether or not selenium was bound specifically to serum lipoproteins to the same degree as vitamin E by estimating the relative concentration of selenium in the various lipoproteins Apparently, both the α- and β-lipoproteins bind selenium-75 with the greater percentage in the α-lipoproteins The presence of selenium in lipoproteins, even though to a much lesser extent than vitamin E, raises the question as to the significance of this trace element in serum lipoproteins Normal dogs, about 20 kg, were injected subcutaneously with $H_2{}^{75}SeO_3$ in dilute hydrochloric acid which contained 1 mc selenium-75 (2 mg selenium) Male rats weighing 100–200 g were injected subcutaneously with a single dose of $H_2{}^{75}SeO_3$ in dilute hydrochloric acid containing approximately 0 2 mc of radioselenium and 40 μg selenium After 24 h whole blood was obtained, allowed to clot at room temperature, and the serum isolated by centrifugation

The lipoproteins were isolated by ultracentrifugation according to the method of DeLalla and Gofman[5] To recover the β-lipoprotein 6 66 ml of the serum were mixed at room temperature with 5 34 ml of a sodium chloride diluent having a density of 1 1364 g/ml The final mixture, with a density of 1 0689 g/ml at 26°, was centrifuged in a Spinco model *LH* preparative ultracentrifuge at 92,660*g* for 22 h Under these conditions, the lipoproteins having hydrated densities of 1 0689 g/ml or less float to the top of the centrifuge tube Paper electrophoresis shows that this fraction is free from albumin Using the Spinco tube slicer the top 2 ml, which contained all the β-lipoprotein, were removed For recovering both the α- and β-lipoproteins, 6 ml of the serum were mixed with a diluent having a density of 1 3884 g/ml (to give a final mixture with a density of 1 2046 g/ml at 26°) and centrifuged at 92,660*g* for 22 h Again, using the Spinco tube slicer the top 2 ml, which contains all the lipoproteins having a hydrated density of 1 2046 g/ml or less, were removed

Electrophoretic analyses were performed in a Spinco model *R* paper electrophoresis apparatus Separation of serum samples was carried out for 16 h at 2 5 m amp in veronal buffer, ionic strength 0 05, *p*H 8 6 in Whatman 3 *MM* paper strips The strips were then oven-dried at 120°–130° for 30 min and afterwards dyed with either bromphenol blue or oil-red-*O* The Spinco Analytrol recording densitometer and automatic integrator was used to evaluate the relative amounts of proteins in the stained material separated electrophoretically Protein-bound selenium was determined by the trichloroacetic acid method in which 20 per cent trichloroacetic acid was used as the protein precipitant, and the precipitate was washed twice with 10 per cent trichloroacetic acid The assay of selenium-75 was carried out in a well-type Berkeley scintillation detector[4]

In preliminary work the lipoproteins from serum were located on paper electrophoretic strips prior to counting by staining with oil-red-*O* Since there is considerable overlapping of serum lipoproteins with other serum proteins with this method, it was abandoned in favour of isolating the lipoprotein themselves by ultracentrifugation Under these conditions the radioactivity could be detected directly in a scintillation counter, with paper electrophoresis being used only as a method to determine the degree of homogeneity of the isolated lipoproteins

The results (Table 1) show that a small but significant percentage of the total serum protein-bound selenium is bound to lipoprotein Both the α- and β-lipoproteins of dog and rat serum bind selenium-75, with the greater percentage in the α-fraction In the dog, 3 58 per cent of the total serum selenium-75 is bound to the lipoproteins of which 2 23 per cent of the total serum selenium-75 is found in the α-lipoprotein and 0 58 per cent is found in the β- or α-2-lipoprotein In the rat 8 83 per cent of the total serum selenium-75 is bound to lipoproteins, of which 5 74 per cent of the total is found in the α-lipoprotein and 4 86 is found in the β-lipoprotein

Comparing the concentration of selenium and vitamin *E* in lipoproteins, we find striking differences in the concentration of these two substances For example, Lewis *et al* [2] showed that 74 per cent of the total serum tocopherol was bound to the lipoproteins in the human Of this, 54 per cent was bound to the α-lipoprotein and 20 per cent to the β-lipoprotein Investigations indicate that vitamin E and selenium have related antioxidant properties[6–9] In vitamin E deficiency peroxidation is widespread and is particularly damaging to the mitochondria and microsomes of the cells where lipid-free radical intermediates react at random with structural and functional proteins, lipids and other compounds The working hypothesis for vitamin E function is that it inhibits *in vivo* lipid peroxidation by reacting with free radical intermediates and with lipid peroxides Tappel *et al* [9] believe that the partial replacement of vitamin E by selenium compounds can occur in some animals because McConnell *et al* [10] have shown that selenium is incorporated into tissue proteins found in the mitochondria and microsomes where, because of their antioxygenic activity, they protect other compounds against *in vivo* peroxidation

Bieri[7] and Zalkin *et al* [9] have observed that dietary selenite, like vitamin E, inhibits *in vivo* lipid peroxidation in liver, heart and skeletal muscles of chickens on a vitamin E deficient ration Tissue antioxidant activity following administration of small amounts of selenium, cystine and vitamin E provides a possible explanation for the similar biological effects of these chemically diverse substances[11] Therefore, it is conceivable that in serum lipoproteins selenium compounds may act as antioxidants as they do in the tissues Lindgren *et al* [12], using gas chromatography, demonstrated a relatively high degree of unsaturation in the fatty acids of triglycerides, cholesterol esters and phosphotides

Whether the selenium molecule is bound in such a way as to be available as an antioxidant will be investigated at a later date Future work is being contemplated to determine whether the selenium was taken up by the protein or the lipid moiety or both

Investigations were carried out on dogs and rats to determine whether selenium was bound to serum lipoproteins A small fraction of the total protein-bound selenium was found in lipoproteins Both the α- and β-lipoproteins bind selenium-75 with the greater percentage in the α-lipoproteins A possible significance of selenium in serum lipoproteins is discussed

IN VIVO INDUCED OXIDATION BY ADRENOCORTICOTROPHIC HORMONE OF REDUCED PYRIDINE NUCLEOTIDE IN THE ADRENAL CORTEX OF HYPOPHYSECTOMIZED RATS

By Dr. BRITTON, CHANCE, B. SCHOENER and Dr J J FERGUSON, jun

Johnson Research Foundation and Department of Biochemistry, University of Pennsylvania, School of Medicine, Philadelphia

METHODS have been described for measuring the fluorescence intensity of an 18-μ area of tissues in anæsthetized rats[1,2] More recently a method has been improved so as to permit the recording of fluorescence emission spectra from a 30-μ area[3]

In this article we describe a large decrease of fluorescence of the adrenal gland of hypophysectomized rats following the injection of a small amount of adrenocorticotrophic hormone (ACTH) into the vena cava of the anæsthetized animal The emission spectra corresponding to the change, the kinetics of the change, its sensitivity to the concentration of ACTH, and the concentration of ACTH giving half-maximal effects are described These results are correlated with independent chemical studies of corticosteroid secretion from the adrenal gland

The experimental methods are identical to those described elsewhere[1-4] In this series of experiments a 30-μ aperture was used In those experiments not requiring a recording of spectra, a broad secondary filter peaking at 450 mμ and giving half-maximal response of 400–500 mμ was used[4]

The rats were anæsthetized with 1 gm /kgm urethane, the adrenal cortex was cleared of fat The kidney and the adrenal were held very nearly motionless on a small platform The microscope was focused on the surface of the exposed adrenal gland, close to, but not coincident with, the region where the larger blood vessels are located The field appeared to be uniformly and brightly fluorescent in the hypophysectomized animals

As described previously, fluorescence intensity is recorded as a function of time or wave-length[3] The

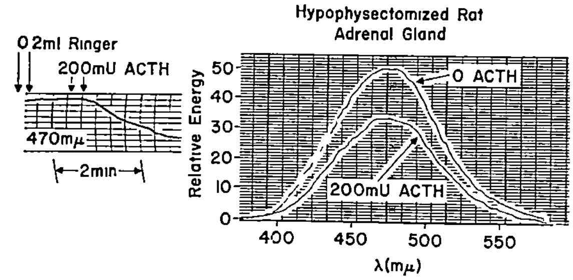

Fig 1 Emission spectra obtained with microspectrofluorometer focused on adrenal cortex of hypophysectomized rat (urethane anæsthesia) 366 mμ excitation, 30-μ observation aperture The upper spectrum represents the fluorescence emission with the rat breathing oxygen and prior to the injection of ACTH The inset on the left represents the time-course of changes following the injection of 0 2 ml Ringer solution and then 200 mU ACTH into the vena cava The decrease of fluorescence is indicated by a downward deflexion The spectrum labelled 200 mU ACTH is recorded after the effects of ACTH have reached a plateau The energy distribution is referred to a cæsium antimony photosurface and does not represent the absolute distribution of energy

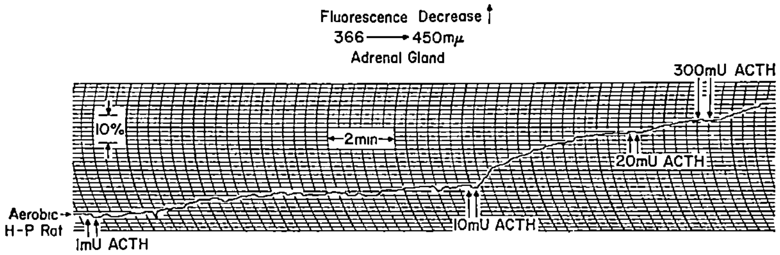

Fig. 2. Time-course of the effect of low concentrations of ACTH. Here the microfluorometer is used at a fixed wave-length with a broad-band secondary filter with a maximum at 450 mμ. The record shows the effects of 1, 10, 20 and 300 mU of ACTH on the fluorescence emission of the rat adrenal gland. Other experimental conditions similar to those of Fig. 1. A fluorescence decrease in this trace is indicated as an upward deflexion. Time proceeds from left to right

intensity at 470 mμ is recorded first as a function of time in order to ensure that experimental conditions are stable. Then, the wave-length drive is engaged and a spectrum is recorded in the region 400–600 mμ. The wave-length is reset to 470 mμ and ACTH is injected. After a plateau is reached, the spectrum is again recorded (Fig. 1).

Hypophysectomized male Sprague–Dawley rats weighing about 200 gm were obtained from Hormone Assay Laboratories, Inc., Chicago, Illinois, and were used 2–4 days after hypophysectomy. Hydrocortisone ('Cortef', Upjohn), 1 mgm, was injected intraperitoneally prior to adrenal exposure.

Commercial ACTH (Armour Laboratories 'Corticotropin') was used, and the manufacturer's batch assay data were utilized. The lot used was stated to contain 20 mU 'Pressor Material' per unit of ACTH. Independent controls showed 30 mU pitressin caused increased reduction of pyridine nucleotide. Thus, the observation of oxidation of pyridine nucleotide could not likely be due to the pressor content of ACTH.

Spectrum of the fluorescence change caused by ACTH. Fig. 1 represents an emission spectrum of the rat adrenal gland indicating the distribution of fluorescence energy prior to the injection of ACTH. The peak of the emission spectrum lies at approximately 475 mμ. Following the recording of the spectrum the monochromator was set back to 470 mμ and the time recording is shown on the left-hand side of the diagram. (Time proceeds from left to right.) Injection of 0·2 ml. Ringer's causes no measurable effect, but almost as soon as the injection of 200 mU of ACTH in 0·2 ml. Ringer's is complete, a downward deflexion of the trace occurs, which approaches completion in about 1·5 min. (A downward deflexion of the trace in this particular record corresponds to a diminution of fluorescence.) At this time, a second spectrum is run (200 mU ACTH), and it is seen that the fluorescence intensity has the same maximum but the intensity has diminished about 40 per cent.

Time-course of ACTH effect. In addition to the insert in Fig. 1, which indicates the rapid response to a high concentration of ACTH, we include in Fig. 2 the time-course of the response to small concentrations of ACTH. The experimental conditions are similar to those of Fig. 1, except that the monochromator for the fluorometer is not used and the secondary filter already described here is utilized. Time proceeds from left to right in the trace, and a fluorescence decrease corresponds to an upward deflexion. The experimental record begins with the hypophysectomized rat breathing oxygen. Double arrows indicate the initiation and completion of the injection of 1 mU ACTH into the vena cava. After approximately 1 min., the trace clearly shows an upward deflexion which reaches its half-maximal level in approximately 2 min. after the injection. After the plateau value has been established, 10 mU ACTH is injected and the trace deflects upwards at a much more rapid rate, the time for half-maximal effect being approximately 1 min., with the plateau value being established in approximately 5 min. Injections of 20 and 300 mU ACTH cause only small further changes.

ACTH concentration required for half-maximal effect. Although the concentration of ACTH giving half-maximal effect varies somewhat from preparation to preparation, more sensitive responses are obtained during the few days after hypophysectomy, and such a result is indicated in Fig. 3. Here, we have plotted the decrease in fluorescence as a percentage of the initial value against the logarithm of the ACTH concentration and find that half-maximal effect is obtained at 1·0 mU of ACTH. It is apparent from this curve that 0·1 mU could be detected, and this has been confirmed in other experiments. [*Note added in proof.* Drs. D. H. Nelson and G. F. Cahill have indicated in personal communications that a greater sensitivity is obtained a few hours after hypophysectomy. Recent experiments at 24 h. after hypophysectomy show half-maximal effect at 0·3 mU with 0·02 mU giving a detectable response.]

Correlation with corticosteroid production. Data from other laboratories on corticosteroid production in rat adrenals indicate that 0·02 mU can be detected and routine assays are carried out in the range 0·04–0·64 mU (ref. 5). The rate of corticosteroid production increases with the ACTH concentration at least up to 0·64 mU (ref. 5) or to 1 mU (ref. 6). Fig. 4 compares the time-course of the fluorescence decrease observed

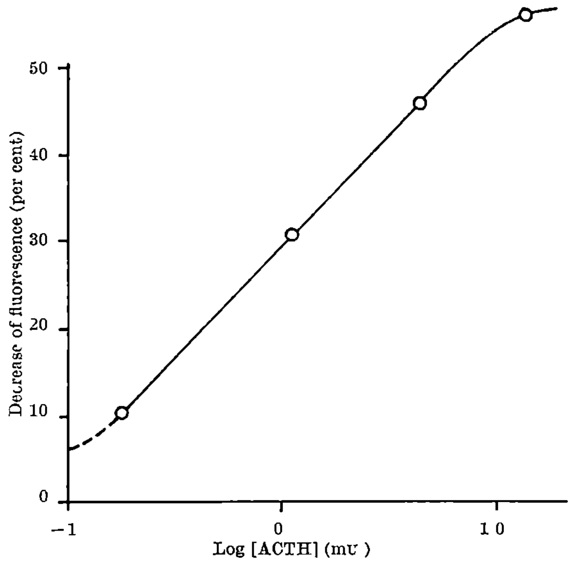

Fig. 3. Fluorescence response of the adrenal gland of the hypophysectomized rat to ACTH concentration. The values of the abscissa represent the logarithm of the total milliunits of ACTH injected and the ordinates represent the percentage decrease of the fluorescence prior to the injection of ACTH. Other experimental conditions similar to those of Fig. 2

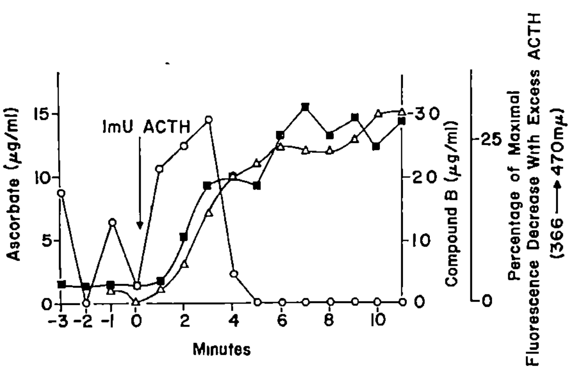

Fig 4 Correlation of adrenal fluorescence decrease and chemical assays of Lipscomb and Nelson (ref 6) for ascorbate and compound *B* released into adrenal vein caused by the injection of 1 mU of ACTH into the hypophysectomized rat
○, Ascorbate (Lipscomb and Nelson), ■, compound *B* (Lipscomb and Nelson), *Δ*, adrenal pyridine nucleotide

in these experiments with the time-course of compound *B* and ascorbate formation found by Lipscomb and Nelson[6] Assuming that the experiments on the two different animals are comparable, the correlation between the fluorescence decrease and the formation of compound *B* is as striking as is the lack of correlation with the formation of ascorbate However, simultaneous measurements on a number of animals are highly desirable in order to confirm this correlation

The change of the fluorescence emission spectrum caused by ACTH injection identifies the oxidation of reduced pyridine nucleotide as a primary biochemical response of the adrenal cortex *in vivo* A number of alternatives need to be considered in determining the biochemical origin of the changes First, this change resembles that observed in a resting-active transition of isolated mitochondria, which corresponds to an oxidation of reduced pyridine nucleotides of approximately the same fraction of the total (50 per cent)[7,8]

Note added in proof The histochemical studies of Greenberg and Glick[9] show a large increase of oxidized pyridine nucleotide (~ 40 per cent) in the glomerulosa, in agreement with our data However, they fail to find a statistically significant change of reduced pyridine nucleotide which is to be expected on the basis of our data Apparently more detailed histochemical assays for reduced pyridine nucleotide are desirable

However, the special role of triphosphopyridine nucleotide (TPN) must be considered Post-mortem chemical assays show a relatively small TPN concentration of this gland[10] Assuming that the post-mortem analytical results have validity *in vivo*, the low TPNH concentration in the normal animal (ACTH causes no further oxidation in our experiments with normal rats) indicates that TPNH was not the material oxidized in the experiments of Figs 1 and 2 The large concentration of diphosphopyridine nucleotide (DPN) in the normal animal indicates that oxidation of DPNH is consistent with the experimental observation *in vivo* (Assays based on quick freezing of rat liver[11] show the TPNH/TPN and DPN/DPNH ratios are higher *in vivo* than post-mortem) Present theories suggest that the prime effect of ACTH is on glycogen breakdown and the formation of TPNH by glucose-6-phosphate dehydrogenase, the initial effect of such a mechanism would be a reduction of TPN (ref 11) It is clear that if this effect occurs, it is too small to be observed in our studies In these experiments we observe the net oxidation of reduced pyridine nucleotide, which, of course, does not rule out simultaneous reduction of TPN at glucose-6-phosphate dehydrogenase and oxidation of TPNH and DPNH elsewhere in the cytoplasm and mitochondria Whether or not this net oxidation is due to increased intracellular ADP and phosphate-levels at the mitochondria reflecting increased energy requirements in the adrenal gland or to oxidation of TPNH in steroid hydroxylation in the cytoplasm cannot be resolved at the present time

ULTRASONIC RELAXATIONS IN AQUEOUS SOLUTIONS OF ALIPHATIC AMINES

By J F McKELLAR* and J H ANDREAE†
Akers Research Laboratories, Imperial Chemical Industries, Ltd , Welwyn, Herts

A NUMBER of aqueous solutions of non-electrolytes exhibit a maximum in their 'excess' sound absorption at intermediate concentrations Several workers[1-3] have given explanations for this effect In particular, Schneider[4] has put forward an interesting explanation for the alcohol–water mixtures This involves perturbation by the sound field of the equilibrium

$$AA + BB \rightleftharpoons 2AB \qquad (1)$$

where $AA \equiv$ hydrogen bonded solute molecules, $BB \equiv$ hydrogen bonded water molecules and $AB \equiv$ hydrogen bonded complex between unlike molecules

Barfield and Schneider[5] have interpreted the 'excess' absorption in diethylamine–water in terms of this mechanism

We have found that, for a number of aqueous solutions of non-electrolytes, the 'excess' absorption gives rise to relaxations at frequencies above about 20 Mc/s An account of the relaxations obtained with the amines diethylamine, triethylamine, methyldiethylamine and *n*-amylamine will be the subject of this article

---

* Now at Imperial Chemical Industries, Ltd , Dyestuffs Division, Manchester 9

† Now at Standard Telecommunications Laboratories, Ltd , London Road, Harlow, Essex

The ultrasonic techniques have been described[6] The frequencies used were 1 5, 4 5, 7 5, 13 5, 30, 70, 110 170 and 230 Mc/s Sound velocity measurements were made with an acoustic interferometer operating at 2 Mc/s

For the primary and secondary amines, the measurements α/f^2 were described by the relation for a single relaxation

$$\frac{\alpha}{f^2} = \frac{A}{1 + (f/f_c)^2} + B \qquad (2)$$

where α is the absorption coefficient, f is the frequency of measurement, A and B are constants and f_c is the relaxation frequency Values of $\mu_{\max}$, the maximum absorption per wave-length, defined by

$$\mu_{\max} = \tfrac{1}{2}A\ f_c\ C \qquad (3)$$

were calculated C is the sound velocity

For diethylamine-water the results extend the measurements of Barfield and Schneider[5] into a region of relaxation at higher frequencies, and cover the concentration range over which the excess absorption is readily measured The variation of $\mu_{\max}$ with concentration is shown in Fig 1 The variation of $\mu_{\max}$ and f_c with temperature at a mole fraction of 0 1 diethylamine is shown in Fig 2*a* The temperature dependence of $\mu_{\max}$ and f_c for *n*-amylamine–water is similar to that found with diethylamine For methyldiethylamine-water the results are of particular interest and require further explanation

Previous workers[2,7] have shown that, within the frequency-range 0 6–52 3 Mc/s, α/f^2 at intermediate concentrations of triethylamine–water, decreases rapidly with increasing frequency Further, it was found that α/f^2, measured at a constant frequency, increases rapidly with temperature until the lower critical solution temperature (18° C) of the mixture is reached This dependence on temperature of α/f^2 is quite distinct from that found with diethylamine–water[5] (and from the corresponding behaviour of $\mu_{\max}$ shown in Fig 2*a*)

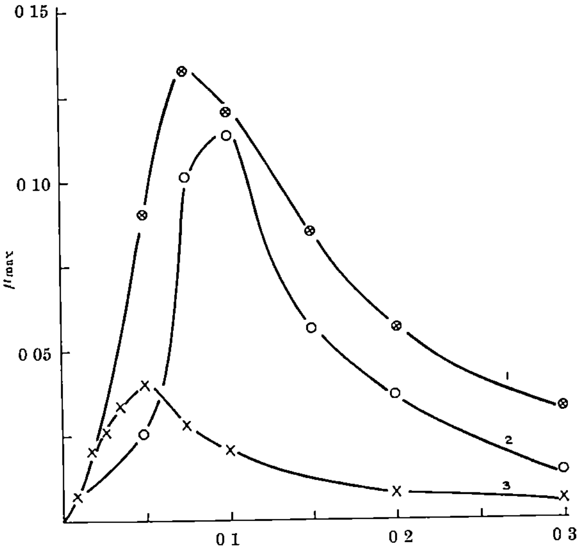

Fig 1 Variation of $\mu_{\max}$ with concentration (1) methyldiethylamine + water (0 0 °C), (2) diethylamine + water (0 0 °C), (3) *n*-amylamine + water (5 0 C)

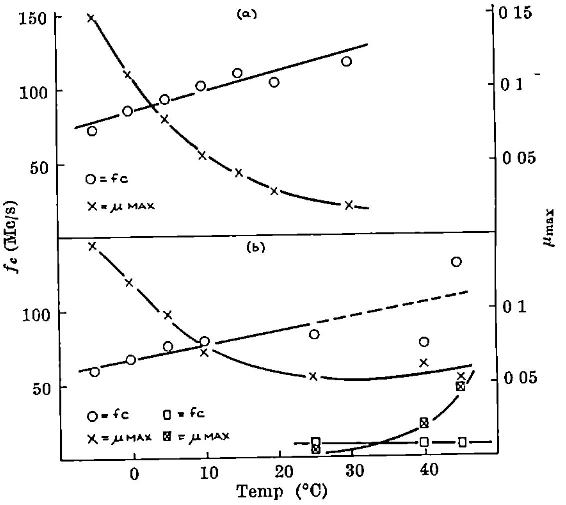

Fig 2 Variation of $\mu_{\max}$ and f_c with temperature (*a*) mole fraction of diethylamine = 0 1, (*b*) mole fraction of methyldiethylamine = 0 1

Measurements were taken in triethylamine–water at 0° C and 15° C at frequencies between 1 5 and 230 Mc/s in order to cover the frequency range in which the single relaxational behaviour is obtained with the other amines Analysis of the results showed that they could not be described satisfactorily by (2) Instead, they were described approximately by the corresponding relation for a double relaxation

$$\frac{\alpha}{f^2} = \frac{A_1}{1 + (f/f_{c2})^2} + \frac{A_2}{1 + (f/f_{c1})^2} + B \qquad (4)$$

The values for A_1, A_2, B, f_{c1} and f_{c2} are given in Table 1

Table 1 CONSTANTS FROM DOUBLE RELAXATION ANALYSIS

Mole fract amine	Temp (°C)	A_1	A_2	B	f_{c1} (Mc/s)	f_{c2} (Mc/s)
		(cm^{-1} sec^2 × 10^{-17})				
		(1)				
0 125	15	24,270	3,770	209	3 9	45
	0 0	4,936	1,993	284	9 7	62
		(2)				
0 10	45	10,760	486	110	6 3	138
	40	3,649	1,138	175	7 9	75
	25	873	884	184	7 2	81

(1) Triethylamine, (2) methyldiethylamine

It is seen that the higher frequency relaxation occurs at frequencies similar to those obtained with the other amines Also, the close proximity of the lower critical solution temperature gives rise to a second relaxation at lower frequencies This makes analysis of the relaxations difficult and prevents a satisfactory examination of their behaviour with temperature It became apparent that, to accomplish this, a tertiary amine was required the aqueous solution of which would have a fairly high lower critical solution temperature so that the higher frequency relaxation in particular could be studied over a fairly wide temperature and concentration-range The system methyldiethylamine–water was chosen (lower critical solution temperature = 49° C (ref 8))

At 0° C, methyldiethylamine–water shows only a single relaxation with relaxation frequency greater than 30 Mc/s The concentration dependence of $\mu_{\max}$ derived from this relaxation is shown in Fig 1 and is seen to be similar to that obtained with the other amines At temperatures above 10° C, however, it was found that the relaxational behaviour could not be described by equation (2) but could be described approximately by equation (4) This situation is therefore similar to that found with triethylamine–water and the constants for the relaxations are also given in Table 1. The variation of μ_{max} and f_c with temperature is shown in Fig 2b for the two relaxations The similarity between the higher frequency relaxation and the relaxation in diethylamine–water is apparent

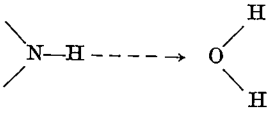
The foregoing results, for aqueous solutions of aliphatic amines, demonstrate the existence of two types of relaxation in the frequency range 1 5–230 Mc/s Possible mechanisms for these relaxations will be considered briefly

The first, which occurs at frequencies less than 10 Mc/s, is only observed when the temperature is close to the lower critical solution temperature of the mixture This suggests that some phase separation process is responsible Brown and Richardson[9], however, have shown that considerable sound scattering occurs in binary mixtures when these are at temperatures close to their consolute temperature In addition, our measurements, which terminate at 1 5 Mc/s, do not cover the whole region of the lower frequency relaxation In view of these factors, therefore, further analysis of the sound absorption data for this relaxation is likely to be difficult and we shall not consider this relaxation further

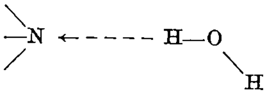
The second, which occurs at frequencies greater than 30 Mc/s, is observed with primary, secondary and tertiary amines This suggests that the mechanism responsible for the relaxation is one which is common to the three types of amine Following Schneider[4], we shall consider that the relaxation is due to perturbation of an equilibrium involving hydrogen bonding between unlike molecules However, the observations with the tertiary amines, for which the majority existence of the amine in the form of hydrogen-bonded dimers seems unlikely[10], causes us to reject the equilibrium (1) in favour of the simpler

$$A + B \rightleftharpoons AB \qquad (5)$$

In the case of the primary and secondary amines, hydrogen bonding in the complex AB can occur in two possible ways, shown diagrammatically by



(a)



(b)

The observations with the tertiary amines further suggests that the hydrogen bonding of the complex AB occurs by (b)

EFFECT OF CERTAIN PHENOLIC ACIDS ON THE ELONGATION OF *AVENA* FIRST INTERNODES IN THE PRESENCE OF AUXINS AND TRYPTOPHAN

By J. H M HENDERSON* and J P NITSCH

Le Phytotron, Gif-sur-Yvette (Seine-et-Oise)

SEVERAL reports in the literature[1–5] have pointed out the synergistic role certain phenolic compounds can have in auxin growth responses It has been demonstrated that such compounds can interfere with the metabolism of 3-indolylacetic acid (IAA) (ref 6) Some of these reduce its destruction by IAA-oxidase polyphenols, especially ortho-diphenols such as caffeic and chlorogenic acids[7–9]. Others enhance IAA destruction and act as co-factors of IAA oxidase monophenols such as *p*-coumaric acid[10,11] In addition, certain phenols have been shown to increase the yield of IAA produced from tryptophan[12]

In the first internode test, numerous compounds act synergistically (that is, they promote more than an additive response) with IAA (ref 13) This effect could be due to the sparing of IAA or to the formation of a complex biologically more active than IAA. In order to elucidate this point, the following experiments have been made in regard to the first of these possibilities

(I) Auxin Experiments

(1) *Differential response to IAA, NAA and* 2,4-*D* Experiments were conducted in the same manner as described by Nitsch and Nitsch[13] for the *Avena* first internode test Concentrations of IAA ranging from 10^{-8} to 10^{-5} M were used Chlorogenic acid was used as the synergist at the concentration (10^{-4} M) shown to be most effective in a previous investigation[3] These results are shown in Fig 1 The lower growth at 10^{-5} M IAA was probably due to inhibiting concentration of IAA Similar results were obtained with coleoptiles The results confirm the previous reports that chlorogenic acid acts synergistically with IAA in promoting the elongation of oat first internode sections

Similar tests were made with two other auxins, 1-naphthylacetic acid (NAA) and 2,4-dichlorophenoxyacetic acid (2,4-D), at the same molar concentrations as IAA The results are summarized in Table 1 These experiments have been repeated several times In no case was the elongation produced by 2,4-D affected by chlorogenic acid, whereas on two occasions

---

* Present address Carver Foundation and Department of Biology, Tuskegee Institute, Ala , U S A

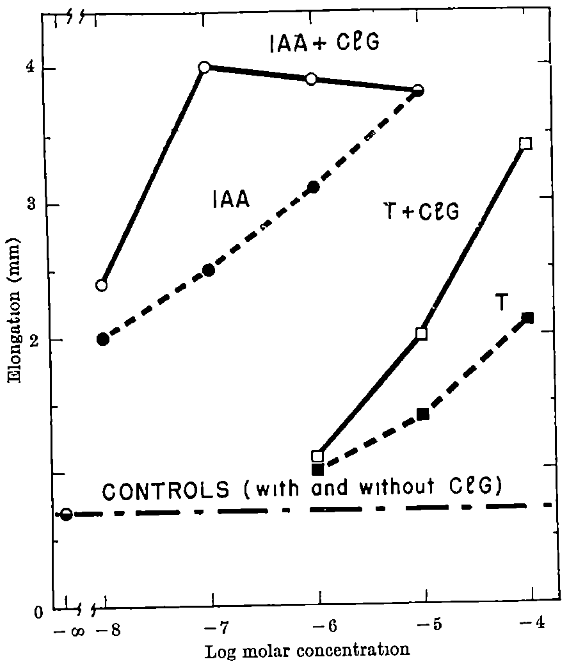

Fig 1 Elongation of *Avena* first internodes (var Brighton) in the presence of various molar concentrations of 3-indolylacetic acid (IAA) and L-tryptophan (T) with (solid lines) and without (dotted lines) chlorogenic acid (ClG) at the concentration of 10^{-4} M Initial length of sections 4 mm growth measured after above 20 h of incubation Each point is the average of two sets of 10 replicates each

the NAA results seemed to show a slight synergism. However, in comparison with the synergism shown by chlorogenic acid with IAA, the results with the other two auxins are negative There is the report in the literature by Reinders-Gouwentak and Smeets[2] that NAA acts as a synergist with ferulic and caffeic acid However, it would be unlikely that NAA could be involved in a system which is concerned with IAA economy through IAA-oxidase or a similar mechanism of destruction

In any event, the general lack of synergism observed with NAA and 2,4-D confirms the earlier results reported for NAA (ref 13), and suggests that the effect of chlorogenic acid is linked to a mechanism which is specific for IAA

(2) *Influence of chlorogenic acid on IAA destruction* In order to answer the question whether chlorogenic acid enhances growth through a sparing mechanism, the IAA remaining after the growth of internode sections was measured Since the IAA concentrations used in the internode test were too low for spectrophotometric detection, the *Avena* curvature test was used For spectrophotometric determinations, higher levels of IAA were used (5–10 μg/c c) The Gordon–Weber reagent[14] was used for the detection of residual IAA The results are given in Table 2

* Absorbancy in arbitrary units from linear chart paper of Beckman *DK*-2 spectrophotometer

† This value is lowered 45 per cent by the presence of chlorogenic acid

From the *Avena* curvature results it would appear that chlorogenic acid preserves a small amount of IAA activity at the higher levels From the spectrophotometric results it is obvious that IAA disappears in the presence of internode sections However, when chlorogenic acid is present in the medium, the level of IAA remains higher (Table 2) Chlorogenic acid in the presence of IAA lowers the absorption (about 45 per cent), possibly in the manner suggested by Platt and Thimann[15]

One may conclude that chlorogenic acid does reduce the disappearance of IAA from the solutions in the presence of first-internode sections

(II) Experiments with Tryptophan

The foregoing results strongly suggest that the first internode sections destroy the IAA which has been added to the solution and that this destruction is reduced when chlorogenic acid is added These results parallel those obtained by Rabin and Klein[7] with a preparation of IAA-oxidase Vendrig and Buffel[16] have recently questioned the likelihood that such a mechanism operates *in vivo* In order to elucidate this point, experiments were performed with a precursor which can be transformed into IAA *in vivo*, namely, L-tryptophan

L-tryptophan, at a sufficiently high concentration (around 10^{-5} M), elicits excellent growth of the mesocotyl section[17] During the incubation period several products are formed in the medium (Henderson, unpublished data) One of these substances is presumed to be IAA, for it has the following characteristics (1) it promotes curvature in Went's *Avena* test, (2) it produces a red colour with the Gordon–Weber reagent with maximal absorbancy in the visible range at 525 mμ, (3) 4–5 times more of the substance is formed when L-tryptophan is incubated at *p*H 7 5 than when it is incubated at *p*H 5 0, (4) an ether extract of the medium shows a spot at R_F 0 30 giving the characteristic pink colour with the Gordon–Weber reagent when chromatographed in isopropanol (80) + ammonia (0 1) + water (19 9) Blanks with the sample of L-tryptophan used did not reveal any contamination with IAA before incubation with the sections

The results in Fig 1 show that chlorogenic acid at 10^{-4} M has a synergistic effect with L-tryptophan as it does with IAA

By using the Gordon–Weber reagent it has been shown positively in six out of nine instances that more IAA is present in the medium containing chlorogenic acid + L-tryptophan than in the medium with L-tryptophan alone, despite the inter-reaction between chlorogenic acid and the reagent as pointed out previously (Table 2) One must consider that in the experiments with L-tryptophan both the synthesis and destruction of IAA are occurring simultaneously and continuously The presence of chlorogenic acid should doubly augment the presence of IAA by enhancing its biosynthesis[12] and by inhibiting its destruction[7]

(III) Antagonism between Mono- and Di-Phenols

The results shown here indicate that chlorogenic acid produces synergistic effects with both IAA and tryptophan Similar results can be obtained with caffeic acid, a component of chlorogenic acid (Table 3) If the promotive effect of these *o*-diphenols is mediated via the IAA-oxidase system, then a monophenol such as *p*-coumaric acid should act as an antagonist Coumaric acid, at the concentration of 10^{-4} M, inhibits the promotion of mesocotyl elongation by IAA (ref 13) When added together with chlorogenic or caffeic acids, it nullified the synergistic effect of these compounds (Table 3) Similar results were obtained with L-tryptophan

Table 3 EFFECT OF CHLOROGENIC (ClG), CAFFEIC (CAF) AND *P*-COUMARIC ACIDS (CUM) AT 10^{-4} M ON THE ELONGATION OF *Avena* FIRST INTERNODE SECTIONS IN THE PRESENCE OF IAA OR L-TRYPTOPHAN

	Additives					
	None	ClG	CAF	CUM	ClG + CUM	CAF + CUM
IAA (10^{-7} M)	22	29	30	13	20	14
L-Tryptophan (10^{-4} M)	16	30	30	19	18	16
Controls	4	7	4	5	—	—

Same experimental procedure as in Table 1 Increased growth of sections in mm (× 10)

The results presented here confirm and extend the results showing that *o*-diphenols such as caffeic and chlorogenic acids enhance the growth produced by IAA, but not that produced by 2,4-D and, possibly, NAA They have a sparing action on the IAA present in solution These phenolics exert a similar synergistic effect on tryptophan, which acts as a precursor of IAA Finally, the work presented here indicates that monophenols (such as *p*-coumaric acid), which act as co-factors of IAA oxidase, can completely nullify the effect of phenolic synergists All these results point towards the inhibition of the IAA-oxidase system as the origin of the synergistic action of polyphenolic compounds

We thank Mrs C Nitsch and Mr M Sandmeier, who assisted in various phases of the work One of us (J H M H) also wishes to thank the National Science Foundation for the opportunity to work at the Phytotron through the award of a Science Faculty fellowship for the year 1961–62

HISTOLOGICAL DISTRIBUTION OF BRAIN GANGLIOSIDES: LYSOSOMES AS GLYCOLIPOPROTEIN GRANULES

By Dr HAROLD KOENIG

Veterans Administration Research Hospital, and Department of Neurology and Psychiatry, Northwestern University Medical School, Chicago

GANGLIOSIDES are acidic, hydrophilic glycosphingolipids that contain *n*-acetylsialic acid Although gangliosides occur in highest concentration in grey matter of brain, they are also present in white matter and seem to exist in other organs Recent observations implicating gangliosides in neural excitability have led to the suggestion that gangliosides are located in the cell membrane of neurones and are involved in ion transport and other aspects of membrane function[1,2] Gangliosides are greatly increased in Tay-Sachs disease, occurring here in granules of distinctive ultrastructure within neuronal cytoplasm[3] Little, however, is known concerning the histological distribution of gangliosides in the normal nervous system

Spherical inclusions are present in neuronal cytoplasm which are periodic acid–Schiff positive[4–6] and stain metachromatically with basic dyes after sulphation[6] These reactions are unaffected by diastase In the course of another investigation[7], I observed that these granules, which also occur in the sparse cytoplasm of glia, and in Schwann, leptomeningeal, adventitial, ependymal and chorioidal epithelial cells, are extracted by brief immersion of fresh nervous tissue in chloroform/methanol (2 1, v/v) at room temperature Formalin-fixation renders these granules resistant to chloroform–methanol and pyridine, even at 60° C for 18 h The inclusions are < 0 2–0 8μ in diameter, occur in dendrites but not axons, and are present in all species thus far examined, namely, rat, cat, dog monkey and man (Fig 1) Neuronal membranes are not stained by the periodic acid–Schiff method No other lipophilic, periodic acid–Schiff-positive constituent is evident in nervous tissue, except myelin lipids and neurokeratin (proteolipid protein)[7]

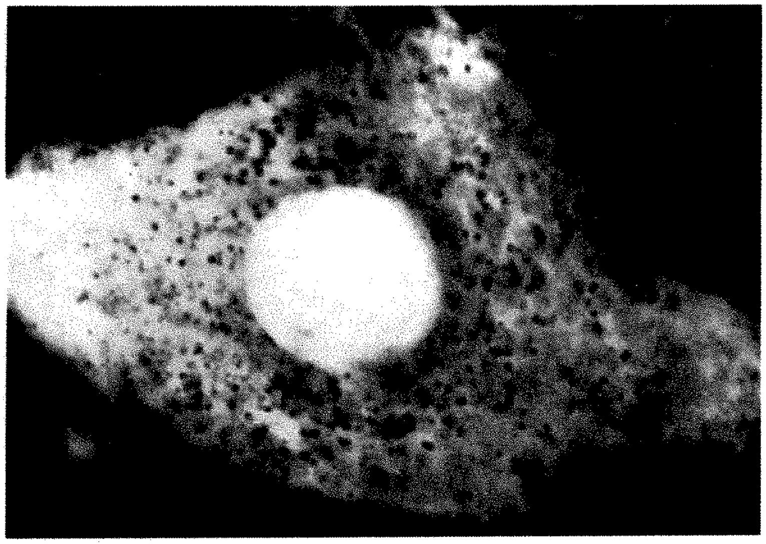

Fig. 1. Motoneurone of cat spinal cord stained by the periodic acid–Schiff method. Frozen section, calcium–formalin fixation. × 1,150

These histochemical properties are characteristic of lipophilic carbohydrate, that is, glycolipid. The lipid insolubility of the carbohydrate moiety after exposure of tissues to protein denaturants indicates that the glycolipid in these granules is complexed with protein. The protein matrix itself, like myelin protein[7], appears to be lipophilic in the undenatured state and thus would contribute to the proteolipid protein fraction[7,8]. Granules with these attributes are therefore designated GLP (glycolipoprotein) granules. Two classes of glycolipids are present in nervous tissue, cerebrosides and gangliosides. Cerebrosides are excluded on the ground that they are myelin sheath constituents, predominate in white matter, and do not survive paraffin-embedding. Gangliosides appear to qualify as the glycolipid moiety of GLP granules on several counts. The acidic character of gangliosides, which derives from *n*-acetylsialic acid, would incline them to form complexes with proteins. It furthermore could confer on GLP granules the negative charge which they seem to bear, judging from the facility with which they are stained intravitally by cationic dyes (*vide infra*). The topographical distribution of gangliosides in brain furthermore resembles that of GLP granules in that both are more plentiful in grey matter than in white matter, a correlation noted earlier[5].

These considerations led me to examine a known ganglioside–protein complex to determine whether it possessed the predicted histochemical properties. Gangliosides ('strandin'), isolated from cat brain by the partition-dialysis method of Folch *et al.*[8], were precipitated from aqueous solution with protamine, a basic protein, and spread on glass slides. The resulting dried films, stained intensely by the periodic acid–Schiff method, displayed strong sulphation-induced metachromasia and resisted extraction by chloroform–methanol. Ganglioside-protaminate thus exhibits the staining and solubility characteristics of GLP granules. Taken together, these observations lead to the conclusion that gangliosides are the glycolipids of GLP inclusions in brain.

Other staining methods appear to stain GLP inclusions. Early workers depicted fuchsiniphil, hæmatoxyliniphil, osmiphil and argentiphil granules in the cytoplasm of neurones ('neurosomes' of Held) and glia ('gliosomes' of Alzheimer) which resemble GLP granules in size, shape and distribution[9,10]. Similar neuronal inclusions are stained by the cationic (basic) dyes, neutral red and methylene blue, applied supravitally or injected *intra vitam*[11]. Baker *et al.*[12] correlated the neutral red inclusions, or 'lipochondria', of neurones with granules which, under appropriate conditions, are stained by heavy metals, acid fuchsin and sudan black B, give positive acid hæmatein and periodic acid–Schiff reactions, and are extracted by hot pyridine. They concluded that lipochondria contain phospholipid and 'cerebroside'. I have found that similar granules can be demonstrated, although inconsistently, by the Gram stain when applied to chromated tissues. There seems little reason to doubt that neuronal and glial granules which are stained by these, and other, methods, and the GLP inclusions discussed here, represent the same cytoplasmic constituents.

Granules with similar tinctorial and solubility characteristics also are present in cells of many other organs, for example, liver, spleen, kidney and intestine[13]. Because the periodic acid–Schiff-positive component of these granules in fixed tissues resists diastase and lipid solvents, it usually is identified as a mucopolysaccharide or mucoprotein[4]. Its extractability from fresh tissues by chloroform–methanol demonstrates clearly, however, that the carbohydrate

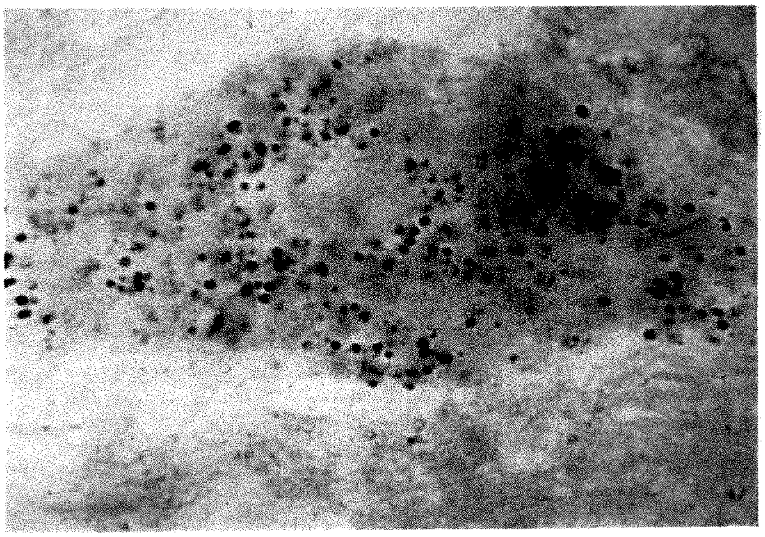

Fig. 2. Motoneurone of cat spinal cord stained for acid phosphatase by Gomori's method. Frozen section, calcium–formalin fixation, × 1,150

moiety is part of a protein-bound glycolipid. The glycolipid may be ganglioside, for gangliosides are present in spleen[14], liver[8] and kidney[15]. These probably differ from brain gangliosides in some respects; thus, they contain considerably less *n*-acyl sialic acid than their counterpart in brain[15]. Even in brain, gangliosides comprise a heterogeneous class of glycolipids[16].

The widespread occurrence of GLP granules suggests that they are a significant constituent of cells in general. It is proposed here that GLP granules are lysosomes, cytoplasmic organelles which contain acid phosphatase, acid deoxyribonuclease and certain other hydrolytic enzymes[17,18]. GLP granules bear a striking morphological resemblance to acid phosphatase granules[19] and acid deoxyribonuclease granules[20] in neurones (Fig. 2). Parallel increases in size and number of GLP granules and acid phosphatase granules have been observed in reactive macroglia and lipid phagocytes in several experimental and spontaneous[21] neural lesions. GLP granules are morphologically similar to acid phosphatase granules in liver, spleen, kidney and small intestine[21]. Acid phosphatase activity has been localized to neutral red inclusions in fibroblasts and astrocytes cultured *in vitro*[22] and to saliva-resistant periodic acid–Schiff-positive inclusions in liver[23]. Acid phosphatase, unlike glycolipid, is displaced or extracted from lysosomes in calcium–formalin fixed tissues by lipid-disrupting procedures[24]. This observation suggests that an appreciable fraction of lysosomal protein may be enzymatically inert. Biochemical studies, furthermore, have revealed a close correlation in the distribution of acid phosphatase and ganglioside-bound *n*-acetylsialic acid in sub-cellular fractions of brain; both constituents occurred in highest concentration in a fraction intermediate between the usual mitochondrial and microsomal fractions[25]. These findings support the inference that GLP granules are lysosomes. They also are consistent with the conclusion presented here that GLP granules in brain contain gangliosides.

The presence of glycolipids in lysosomes excites speculation concerning their role in these organelles. De Duve *et al.*[18] regard lysosomes as inert little bags delimited by a lipoprotein membrane. Their hypothesis ascribes to this membrane the function of restricting the physical freedom and substrate-accessibility of the enclosed enzymes. Release or activation of lysosomal enzymes, according to these workers, results from disruption of the lipoprotein envelope. Ultrastructural studies indicate, however, that although some may be vacuolated, lysosomes are essentially solid organelles[19,26]. Dense inclusion bodies occur in neuronal cytoplasm[27] which probably are lysosomes. Histochemical staining, moreover, indicates that protein-bound glycolipids are distributed throughout lysosomes.

The following hypothesis therefore is offered as an alternative to the membrane hypothesis of de Duve. It is proposed that lysosomes are composed of macromolecules of enzyme and non-enzyme protein conjugated to acidic glycolipids by ionic, covalent, and/or other bonds. The essential inertness of acid hydrolases *in situ* is viewed here as deriving from their sequestration within 'solid' glycolipoprotein complexes. Release or activation of these hydrolases is visualized as an attenuation or cleavage of glycolipoprotein-enzyme bonds, rather than a disruption of a membranous envelope.

It is relevant to inquire whether the action of known releasing agents[17,18] is consistent with this conceptual model of lysosomes. Brain gangliosides, and glycolipids from liver and kidney[15], are soluble in both aqueous and lipid solvents; acid hydrolases are water-soluble. Hypotonic aqueous media, lipid solvents and surface-active agents might reasonably be expected to dissolve lysosomal glycolipid or protein moieties, or both. Freeze-thawing, blenderizing and ultrasonic irradiation bring about a physical fragmentation of lysosomes. The consequent increase in surface area of comminuted particles would promote dissociation or solution of glycolipoprotein complexes. The releasing action of 'thermal activation' and proteases[28] suggests that non-enzyme protein is requisite to the physical integrity of lysosomes and their binding of hydrolases. It also would be anticipated that removal or blockage of the functionally important *n*-acyl sialic acid residue of acidic glycolipids might result in significant release of lysosomal hydrolases. Sialidase, basic proteins and metallic cations are suggested as potential release agents in this category. The results of preliminary experiments support this inference and suggest further that the intravital release of lysosomal enzymes may be responsible for structural and functional disturbances in some disease states[29].

These investigations were supported by grant *B*–1456 (*C*1) and (*C*2) from the National Institutes of Health of the U.S. Public Health Service, contract No. *AT* (11–1)–89 from the U.S. Atomic Energy Commission, and grant No. 304 from the National Multiple Sclerosis Society.

Note added in proof. Since submitting this article, it has been ascertained that the neuronal granules which possess acid phosphatase activity and GLP granules are identical. This was shown by photomicrographic recording of calcium–formalin-fixed sections stained successively by Gomori's glycerophosphate–lead nitrate method and by the periodic acid–Schiff method[13].

A NOTATION FOR ALLOTYPY

By Dr S DRAY
National Institute of Allergy and Infectious Diseases, Bethesda, Maryland

Dr S DUBISKI
Instytut Hematologii, Zaklad Serologii, Warszawa

Dr A KELUS
Department of Experimental Pathology, University of Birmingham

Dr E S LENNOX
Department of Microbiology, New York University, College of Medicine, New York

AND

Dr J OUDIN
Institut Pasteur, Paris

We have agreed on a terminology and notation to be used by us in future publications on allotypy and have established correspondences among already identified allotypic specificities of rabbit γ-globulins[1-13]

Terminology

Allotypy is the property, possessed by certain proteins, of existing in several forms or *allotypes*[14] so far not distinguished by usual physicochemical and chemical criteria, and defined by two kinds of antigenic specificities isotypic and allotypic

The *isotypic*[15] *specificity* is that which is the same in all normal individuals of the same animal species, for example, there are antibodies against rabbit γ-globulin prepared in animals of species other than rabbit (for example, guinea pig), which do not distinguish one rabbit serum from another

The *allotypic specificity* is that which is not the same for all normal individuals of the species, for example, anti-rabbit γ-globulin prepared in some rabbits will precipitate sera of certain rabbits but not of others The fact that an antiserum reacts with some but not all individuals of a certain animal species is necessary but not sufficient to the demonstration of allotypy, for such a fact could be due simply to the presence or absence of the molecules carrying a given isotypic specificity. A demonstration of allotypy must include evidence that the observed immunochemical variation occurs in molecules carrying a common isotypic specificity

The *allotypic formula*, more or less complete according to the test antibodies at hand, of a biological fluid, of a preparation, etc , lists the allotypic specificities looked for and indicates their presence or absence

Immunochemical and Genetic Symbols

The choice of notation was guided by that suggested by Ford for the blood groups[16] Symbols in Roman type designate immunochemical specificities and those in italics refer to the genetic elements controlling these specificities (Table 1)

The *different allotypic specificities* are designated by Arabic numbers In order to avoid any confusion with numbers of quantitative meaning (frequency, etc), the numbers used as symbols are preceded by the capital letter A in Roman type, for example, A1, A2 In two different animal species, the use of the same number does not have any meaning of similarity or correspondence between the allotypic specificities designated by that number, or between the protein molecules which carry these numbered specificities It is assumed that the context will prevent any ambiguity, if not, the symbols of allotypic specificities can be completed by one or two letters designating the species (preferably from its Latin name) and added before the letter A

A *gene* controlling an allotypic specificity designated by a given number is designated by the same number in superscript to the block letter A, both letter and superscript in italics, for example, A^1, A^2

Distinct molecules carrying different allotypic specificities have systematically been found together in sera, as though controlled by the same allele or by closely linked genes In the case of such *families of allotypic specificities*, the family will be designated by a number and the different members of the family by the same number with the superscript ′ (prime) ″ (double prime), for example, A1′, A1″ Should further genetic experiments reveal that such allotypic specificities are controlled by different genes, these specificities would be designated by different numbers

The *locus* to which the gene controlling an allotypic specificity is assigned is designated by a small letter in italics, for example, A^1_a, A^9_b To include the symbol of the locus in that of the allotypic specificity, the symbol will be written, for example, Aa1, Ab9 in ordinary letters

Table 1 SYMBOLS

Meaning	Examples of symbols			Print
Allotypic specificity	A1		A2	Roman
Gene	A^1		A^2	Italics
Families of allotypic specificities	A1′	A1″	A1‴	Roman
Locus				
alone	a		b	Italics
in the symbol of the gene	A^1_a		A^9_b	Italics
in the symbol of the allotypic specificity	Aa1		Ab9	Roman
Genotype	$A^1_b A^1_b$	$A^4_b A^7_b$	$A^6_d A_d$	Italics
	A b($1^+2^-4^-7^-$)	A b($1^-2^-4^+7^+$)	A d(6^+10^-)	
Phenotype*		A b($1^+2^-4^-7^-$)d(6^+10^-)		Roman
		A($1^+2^-4^-6^+7^-10^-$)		
Allotypic formula†		A b($1^+2^-4^+7^+$) d(6^+10^-)		Roman
Allotype	A 3 A c3 A c3/Is X8		A 1,6 A a1d6 A a1d6/Is Y5	Roman

* The first examples of symbols of phenotype (or allotypic formula) correspond to the genotype on the line above The examples on the next lines are symbols of similar or more complete phenotypes expressed with or without the symbols of the locus

† Although the examples on the preceding lines are of either phenotype or allotypic formula, the example on this line is one of an allotypic formula and not a phenotype, since it includes three allotypic specificities controlled by three allelic genes

The *genotype* is written as follows $A_b^1 A_b^1$ or $A_b^4 A_b^7$ or $\mathrm{A}_b^9 A_d$ In the last example, the absence of symbol for the gene means an allele of the locus *d* the product of which is unknown Such a designation would be necessary if the individual is known to be heterozygous at the locus *d* despite the fact that only product Ad9 can be found

The *phenotype* is written with letters in Roman type The inclusion of a symbol of a given allotypic specificity indicates that the reaction suitable for determining the presence of this allotypic specificity has been carried out If this allotypic specificity is present, its symbol is accompanied by the sign + in superscript, or (in the contrary case) by the sign − in superscript, for example, $\mathrm{Ab}(1^{+}2^{-}4^{-}7^{-})$, $\mathrm{Ad}(6^{+}10^{-})$, or $\mathrm{A}(1^{+}2^{-}4^{-}6^{+}7^{-}10^{-})$

Allotypic formulæ In contrast to the phenotype which is characteristic for an individual, any mixtures (artificial, or natural such as those which occur in young animals) of proteins may have assigned to them allotypic formulæ In general, when a given individual is concerned, the allotypic formula is the same as the phenotype The same symbols are used as for designating phenotypes

Allotypes An allotype the molecules of which are known to carry one or more allotypic specificities will be designated, for example, as follows A 3 or A 1, 6, or to include the loci A c3 or A a1d6 The isotypic specificity (Is) of one allotype will be indicated as a denominator, the allotypic specificity (ies) being the numerator, for example, A c3/Is X8 or A a1d6/Is Y5 (the symbols X8 and Y5 are examples only and do not refer to assigned isotypic specificities) Other features characteristic of molecules of the concerned allotype, for example, the sedimentation constant, may also be indicated in the same manner, such as, A b1d10/Is Y8/7S

Present List of Allotypic Specificities in the Rabbit (Table 2)

In order to make correspondences among the allotypic specificities defined in the authors' several laboratories, antisera from these laboratories were tested with suitably chosen normal rabbit sera and their reactions compared in two ways

(1) By reacting them individually with single sera of non-immunized rabbits A criterion that the two antisera contain antibodies directed against different allotypic specificities is the finding of one or more normal sera reacting with one antiserum and not the other On the other hand, the larger the collection of normal sera giving similar reactions with the antisera in question, the stronger the presumption they do contain antibodies against the same specificity

Table 2 ALLOTYPIC SPECIFICITIES SO FAR FOUND IN RABBIT SERA DESIGNATED BY SYMBOLS OF THE PRESENT NOTATION, CORRESPONDENCE WITH THE SYMBOLS PREVIOUSLY USED IN DIFFERENT LABORATORIES

Present notation		Symbols of allotypic specificities previously used in different laboratories		
Allotypic specificity	Locus	Oudin (ref 2)	Dubiski and Kelus (refs 8–12)	Dray (refs 5, 6)
A1	*a*	b	E	L
A2		c	B	J
A3		d	D	K
A4	*b*	a	F	II
A5		g	A	I
A6		f	C	—

(2) By reacting them with one or several normal sera in neighbouring regions of the same gelled medium, the continuity or coalescence of zones of precipitation of these antisera with the same normal serum being another criterion that these two antisera contain antibodies against the same allotypic specificity

Similarity of reactions by the first test implies either the same specificity or the association of more than one specificity in the same sera Similarity of reactions by the second test implies either the same specificity or the association of more than one specificity on the same molecule

The specificities A1, A2, A3, on one hand, and A4, A5, A6 on the other hand, appear to be controlled by six genes belonging to at least two series of alleles The locus to which gene A^1 belongs will be called *a* and that to which gene A^4 belongs will be called *b* There is evidence that A^2 and A^3 belong to *a* and that A^5 and A^6 belong to *b* (refs 2, 5, 6, 8, 9, 10) Definite assignment to these respective loci will await further genetic experiments

CHEMICAL STERILIZATION OF MOSQUITOES

By DR DONALD E WEIDHAAS

Entomology Research Division, U S Department of Agriculture, Orlando, Florida

LABRECQUE[1] has reported that three alkylating agents—aphoxide, hereafter designated as tepa (*tris*(1-aziridinyl)phosphine oxide), apholate (2,2,4,4,6,6-hexahydro-2,2,4,4,6,6-hexakis(1-aziridinyl)-1,3,5,2,4,6-triazatriphosphorine), and aphomide (*N,N′*-ethylene*bis*[*P,P*-*bis*(1-aziridinyl)-*N*-methylphosphinic amide])—caused sexual sterility in both sexes of house flies (*Musca domestica* L), and Weidhaas *et al* [2] showed that they also caused sterility in two species of mosquitoes, namely *Anopheles quadrimaculatus* Say and *Aedes aegypti* (L), when fed to adults in honey solutions These findings offer possibilities for the control or eradication of mosquitoes through the use of induced sterility[3,4] If the release of sterile males into natural populations can be shown to be as effective and practical as it has been with the screw-worm fly (*Cochliomyia hominivorax* (Coquerel)), sterilization by chemicals would be simpler and cheaper than sterilization by γ-radiation, and the facilities required would be more readily movable If sterilizing chemicals could be safely applied to natural populations, control or eradication could be realized by induced sterility without the necessity of rearing and releasing large numbers of insects

Administration of sterilizing chemicals in the adult food would not be a practical method for field use in the control of mosquitoes unless powerful attractants are developed, and other methods of administration might also be more effective for sterilizing laboratory-reared mosquitoes for release The experiments described here were therefore conducted to determine whether larval exposure and tarsal contact would also induce sterility

Experiments on the induction of sterility by exposure in the larval stage were made with *Aedes aegypti* Five hundred larvæ in the late third or early fourth instar were exposed in enamel pans containing 1 litre of tap-water treated with 10 p p m of tepa or apholate After 24 h, food, consisting of powdered dog checkers and yeast, was provided, and the larvæ were left in the treated water until they pupated The pupæ were segregated by sex, as determined by size, moved to untreated water, and allowed to emerge into small holding cages Pupæ from untreated larvæ were also segregated by sex to provide untreated adults for use in mating experiments

While the mosquitoes were still less than 24 h old, 40 treated or untreated males were combined with 40 treated or untreated females in screen cages 7 in wide, 10 in long, and 8 in high Water and honey solution were provided in cotton pads Three to four days were allowed for mating, then the females were allowed to feed on a guinea pig, and two days later egg collections were made The number of eggs laid and the percentage that hatched are given in Table 1

Table 1

Sex treated	Eggs laid	Per cent hatched
	Tepa	
Male	3,700	0
Female	153	16
Both	173	0
Neither	3,482	89
	Apholate	
Male	1,200	7
Female	1,000	53
Both	800	2
Neither	1,200	71

Tepa at 10 p p m completely sterilized males and almost completely sterilized females Normal females mated to treated males laid a normal number of eggs, none of which hatched Treated females mated to either untreated or treated males laid a reduced number of eggs, eggs from those mated to treated males did not hatch, but 16 per cent of the eggs from those mated to untreated males hatched Apholate at 10 p p m was not so effective

Anopheles quadrimaculatus adults were exposed to residual deposits of tepa on 'Masonite'* panels and glass surfaces On 'Masonite' the deposits were prepared by dissolving tepa in ethanol and applying a sufficient amount of solution with a small paint brush to give a deposit of 500 mg/sq ft For the applications on glass the tepa was dissolved in absolute methanol and 1 ml of solution was pipetted into a 3-in glass Petri dish The Petri dish was rotated until the methanol evaporated to give a deposit of 10 mg/sq ft Virgin males or females less than 24 h old were confined on these residues for 4 h Following this exposure various crosses of 40–50 treated and untreated males and females were made in cylindrical screen cages 12 in in diameter and 18 in long After 3–4 days a blood meal (from a guinea pig) was offered, and 2 days later 25 females were placed individually in glass vials containing water for egg deposition The results are given in Table 2

Table 2

Sex treated	Per cent of females laying eggs	Per cent of egg batches with hatch of 60–100 (per cent)	0
	'Masonite' surface		
Male	76	0	100
Female	4	0	100
Both	8	0	100
Neither	88	100	0
	Glass surface		
Male	92	0	100
Female	0	—	—
Both	0	—	—
Neither	84	100	0

Both males and females were completely sterilized by contact with residual deposits Unexposed females mated to males exposed to tepa on either glass or 'Masonite' surfaces laid a normal number of eggs, but none of the eggs hatched When treated females were mated to exposed or unexposed males, only a few females exposed on 'Masonite' and none of those exposed on glass laid eggs None of the eggs from females exposed on 'Masonite' hatched

Another test was run in which virgin, unexposed females less than 1 day old were mated to males which were exposed for 4 h to 10 mg/sq ft of tepa on glass when they were 4 days old These females laid a normal number of eggs, but none of them hatched, which showed that older males could also be sterilized by contact with residues

During June–August, a total of 88 wild females of *Anopheles quadrimaculatus* were collected from day-time resting stations in Lake County, Florida On return to the laboratory 57 of them were exposed for 4 h on 'Masonite' panels treated the preceding day with 500 mg of tepa per sq ft, and the other 31 were used for unexposed controls All females except three had blood or eggs in their abdomens The three that were unengorged were given a blood meal on a human arm 65 per cent of the unexposed females laid a normal number of eggs that hatched normally, 67 per cent of the exposed females laid a normal number of eggs, but not a single egg hatched Thirteen of the exposed females were dissected and the number of times they had laid eggs was determined by counting the ovarian relics Nine had laid their first batch of eggs, three, their second, and one, her fourth or fifth These results showed that older females that had previously mated, fed on blood, and developed partially or completely one to four or five batches of eggs, were completely sterilized by contact with a residual deposit of tepa

ESTABLISHMENT OF FOUR STRAINS OF CELLS FROM INSECT TISSUES GROWN *IN VITRO*

By T D. C GRACE

Department of Microbiology, John Curtin School of Medical Research, Canberra,
and Division of Entomology, C S I R O , Canberra

MANY attempts to grow insect tissues *in vitro* have been made[1], and in the past few years there has been significant progress in the maintenance of cells for long periods[2] In 1960 a strain of cells from ovarian tissue of *Antheraea eucalypti* Scott (Saturniidae) was established, but due to an accident the strain was lost after it had been growing for six months, during which time it had passed through 22–25 generations and had been sub-cultured 18 times

This article reports the establishment of a further four strains of cells from ovarian tissue of *Antheraea eucalypti* As the development of the strains followed similar courses, only one strain will be described

The cultures from which three strains were developed consisted of cells from ovaries of diapausing pupæ of *A eucalypti* which had been dissociated in 0 25 per cent trypsin (Difco trypsin 1 250) in Puck's saline *A* After dissociation, the cells from four ovaries were placed in a Porter flask with 0 9 ml of insect tissue culture medium The other strain developed from cultures of ovaries which were placed in a Porter flask (4 ovaries/flask) with 0 9 ml of medium All the cultures were incubated at 27°–29° C

The medium was changed every 7–14 days for the first 7 months, but after the cells began to multiply rapidly it became necessary to change the medium every 4–5 days and sub-cultures were made at 8–10 day intervals The cells were removed from the bottle for sub-culturing in the following way the medium was removed from the bottles and the cells were washed once in Puck's saline *A* Then 2 0 ml of 0 1 per cent trypsin in Puck's saline *A* was added and the cells incubated at 25° C As soon as a few cells had come free from the glass, 1 0 ml of insect tissue culture medium was added and gently pipetted to free the cells from the glass After centrifugation at 200*g* for 2 min the supernatant was removed and the cells were re-suspended in fresh medium Approximately 50,000–100,000 cells/ml were placed in a 2-oz half-flat medicine bottle with 3 0 ml of medium

The medium used was a modification of that described by Wyatt[3] Its composition is shown in Table 1 The medium was prepared as follows

A was dissolved in 20 ml water, *B* in 30 ml water, *C* in 20 ml water and *D* in 20 ml water The calcium chloride was dissolved separately in a small amount of water and was added after *A*, *B*, *C* and *D* were thoroughly mixed The vitamins were then added The *p*H was adjusted to 6 5 with potassium hydroxide Streptomycin and penicillin were added just before the medium was sterilized through a sintered glass filter (porosity 5) After sterilization, 19 ml aliquots were taken and made up to 20 ml with 1 0 ml of heat-treated (60° C for 5 min) insect plasma from diapausing pupæ of *A eucalypti*

In October 1960 dissociated cells from ovaries of diapausing pupæ were placed in Porter flasks After 48 h the majority of cells had adhered to the surface of the culture vessel About 50 days after the cultures had been initiated, many cells began to show signs of degeneration (vacuoles and fat droplets in the cytoplasm) and by the seventieth day only a few cells were still healthy During the next four months very little cell-growth occurred Ten months (July–August 1961) after the cultures were started, the number of healthy cells increased rapidly, and the first sub-culture was made 12 days after the renewed cell-growth began Sub-cultures were made thereafter at about 14-day intervals for 2 months The early sub-cultures consisted of about 8,000 cells in 0 9 ml of medium on Porter flasks As the growth continued the cells were transferred to 2-oz medicine bottles Since November 1961 sub-cultures have been made at 8–10 day intervals The parent primary cultures of this strain were still growing after 15 months under *in vitro* conditions

The strain described has been established for 5 months and has been sub-cultured 29 times The two other strains which developed from dissociated

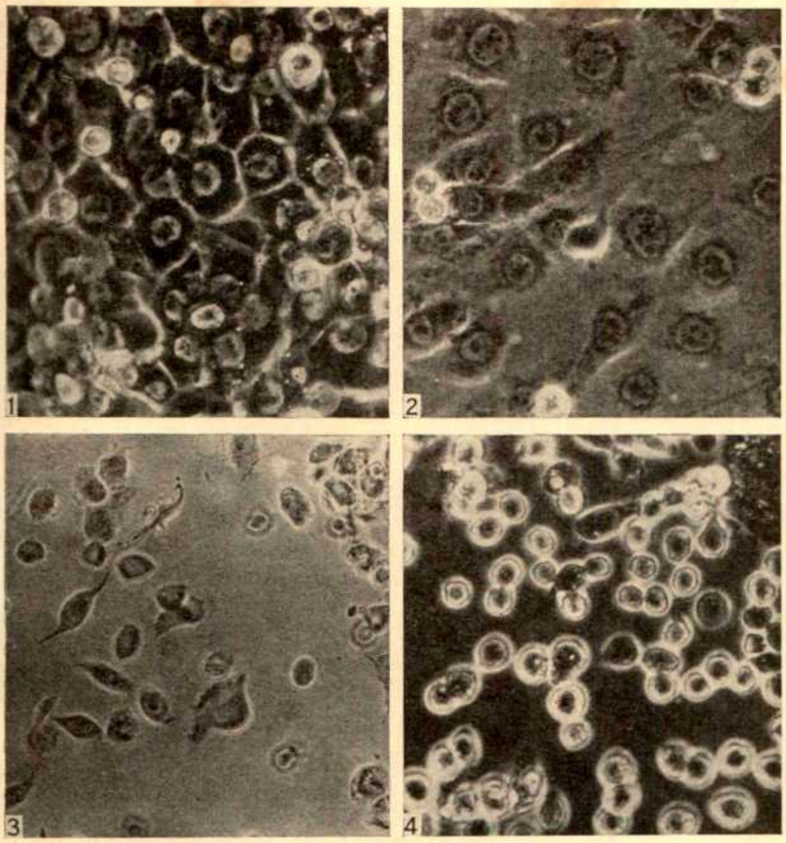

Figs. 1–4. The photographs were taken by phase contrast illumination with a Leica camera attached to a Unitron (model *BU*-13) inverted microscope. Figs. 1, 2 and 3 were taken from a thirty-second sub-culture of *A. eucalypti* ovarian cells and Fig. 4 from a twentieth sub-culture of *A. eucalypti* ovarian cells
Fig. 1, confluent sheet of cells; Fig. 2, type 1 cells 28–40μ diam.; Fig. 3, type 2 cells 16–18μ diam.; Fig. 4, type 3 cells 10–12μ diam.

cells have been growing for 3 months and have been sub-cultured 22 times. The fourth strain, which developed from cultures of undissociated ovaries, has been growing for 8 months and has been sub-cultured 44 times (36 sub-cultures have been made between September 1961 and January 1962).

After sub-culturing, the majority of cells remained floating for 2–4 h and then became attached to the surface of the culture vessel. After 4 days there was usually a confluent layer of cells on the surface of the culture vessel (Fig. 1). Mitotic divisions were numerous and many cells became detached and multiplied while floating in the medium.

The generation time of the cells at the beginning of the development of the strain was about 5–6 days, but since November 1961 the generation time has been 60–72 h. This is appreciably slower than the growth of vertebrate cells grown *in vitro* and may be partly accounted for by the lower temperature at which the cells are grown.

There are three distinct cell types present in the strains. One cell type is common to all four strains (Type 1). This cell (20–40μ in diameter) is polygonal in outline, rather flat and the cytoplasm is finely granulated. Usually, these cells form sheets which adhere strongly to the surface of the culture vessel (Fig. 2). The second type of cell (type 2), which is found in three of the strains, is round to fibroblastic in profile (15–20μ diameter) with a distinct outline and a finely granular cytoplasm. Many of these cells grow in small groups on the culture vessel, but they also multiply while floating free in the medium (Fig. 3). The third type of cell (type 3) is small and round (10–15μ in diameter) with a clear outline and a clear cytoplasm (Fig. 4). This cell type, which is predominant in only one strain, shows very little variation in size or shape and the cells tend to remain loosely attached to the surface of the culture vessel. All three types of cell multiply.

The establishment of the four strains has followed the course frequently observed in vertebrate tissue culture, where it is common for freshly explanted tissues or cells to undergo a period of growth followed by a period in which cell growth slows down or may stop altogether. This period may then be followed by a sudden renewal of growth, and in many instances the cells continue to proliferate for years.

The three other strains developed from cultures set up in August 1960, January 1961 and March 1961. The cultures set up in August 1960 contained undissociated ovaries; the other cultures consisted of dissociated cells. Contrary to results previously obtained[1] the action of trypsin had no adverse effect on the cells. A number of cell types was liberated on dissociation and it is probable that cells other than those from the ovariole sheath have continued to grow in culture[2,4,5].

In establishing these lines of cells certain principles have emerged. Whenever possible the medium should contain plasma from the insect the tissues of which are cultured, and that regard should be taken of the osmotic pressure, pH and ionic ratios of the blood, and these factors be altered in the medium where necessary. If it is not practical to obtain a sufficient supply of homologous plasma it is suggested that plasma from the silkworm (*Bombyx mori*) be used. In my experience, cells from several species of Lepidoptera have grown well and survived for many months when grown in media containing silkworm plasma. The incorporation into the medium of insect hormones (in the form of brain extracts, ring gland extracts, etc.) has not increased growth, but neither have these tissue extracts had any deleterious effect on the cells.

Cells from the strains have been deep-frozen in 10 per cent glycerol in tissue culture medium at −68° C and successfully regenerated.

A limited number of cultures of cells from the strains can be made available to interested workers.

I thank Dr. M. F. Day for his advice.

This investigation was supported in part by research grant *E*-2462 from the U.S. Public Health Service.

PHYSICS

An Isotope Effect in the Probability of ionizing a Molecule by Energy Transfer from a Metastable Noble-Gas Atom

Excitation of a molecule to an electronic state lying above the ionization potential need not result in ionization. The excitation energy can instead be degraded in a re-organization of the positions of the constituent atoms—by dissociation, predissociation, or internal conversion. This conclusion stems from the fact that the fraction of excitation acts leading to ionization; the 'efficiency of ionization', $\eta(E)$, is almost always substantially smaller than unity, at least when the excitation energy, E, is not more than 15–20 eV greater than the lowest ionization potential. Experimental values of $\eta(E)$ for many diverse molecules have been obtained, both for excitation by absorption of a photon[1] (η_p) and for excitation by collision of the second kind with an excited atom[2] (η_c). No information is available for the equally interesting case of excitation by electron impact.

Whether there is true competition in the transient excited state between pre-ionization and atomic re-organization is an important question which is raised but not resolved by these results. The two processes are not necessarily competitive : η might measure the probability of pathways that invariably lead to ionization, as distinguished from pathways that invariably do not. In a simple model, with only two alternative initial steps:

AB + excitation energy $E \rightarrow AB^+ + \varepsilon^-$ [direct ionization, probability δ] or

AB + excitation energy $E \rightarrow AB^*$ [excitation, probability $(1-\delta)$], the latter followed by:

$$AB^* \begin{array}{l} \nearrow AB^+ + \varepsilon^- \text{ [pre-ionization, rate } k_1\text{]} \qquad (1) \\ \searrow A \quad + B \text{ [atomic reorganization, rate } k_2\text{]} \qquad (2) \end{array}$$

it follows that:

$$\eta = \delta + (1-\delta)\, k_1\, (k_1 + k_2)^{-1}$$

(Here AB denotes the molecule; neither A nor B need be monatomic.) Thus it is conceivable that $k_1 \ll k_2$ and hence $\eta \approx \delta$, in which event processes (1) and (2) would not be competitive.

That the contrary is generally true is suggested strongly by arguments in a previous paper[2], which concludes that, indeed, $\delta \ll 1$ is the typical behaviour, and $\eta_c \approx \eta_p \approx (1 + k_2/k_1)^{-1}$ does measure a true competition.

The existence of these competitive pathways in the decomposition of AB^* can be tested by observing the effect on η of isotopic substitution in the molecule. Parameters determined by purely electronic re-organization—δ and k_1—should be unaffected thereby. But k_2 should be diminished, and η therefore increased, if heavier masses are substituted. Thus, $k_2 = k_2' M^{-1/2}$, and:

$$\eta = \delta + (1 - \delta)(1 + M^{-1/2} k_2'/k_1)^{-1} \qquad (3)$$

where M is an effective reduced-mass for such atomic motions as bring the molecule to a point in co-ordinate space subsequent to which pre-ionization is impossible. This experiment has been performed. The predicted isotope effect is found, and in the anticipated sense: in every case the isotopic molecule with heavier atoms has a greater value of η_c. Hence pre-ionization and 'atomic reorganization' are truly competitive.

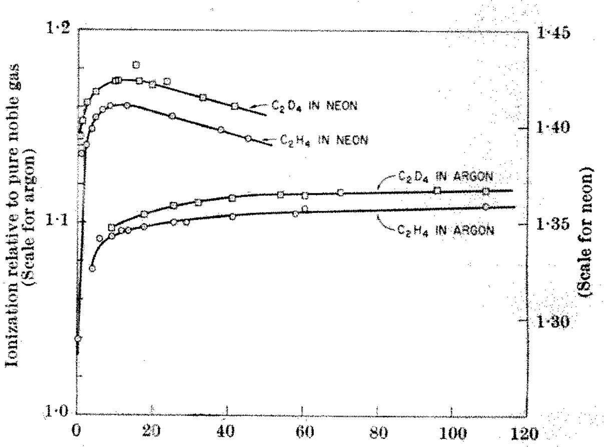

Fig. 1. Ionization current in the mixture, relative to that in the pure gas, plotted against contaminant concentration, for normal and for fully deuterated ethylene in neon and in argon

Measurement of η_c is accomplished by observing the total ionization produced by absorption of high-energy particles in a noble gas contaminated with the molecule under study[2,3]. The ionization exceeds that in the pure noble gas if the latter's lowest excitation energy, E_0, exceeds the ionization potential, I_x, of the contaminant, chiefly because of ionization of contaminant molecules in collisions with metastable noble-gas atoms[4-6]. For all monatomic contaminants this augmentation, ΔN_i, is about the same, although there are small differences which arise from the effect of sub-excitation electrons[7]. Molecular contaminants exhibit large differences in the collateral ionization, for η_c is peculiar to the individual contaminant molecule, and it may lie anywhere between 0 and 1. The value of η_c is given by[2] $\eta_c \approx \Delta N_i/\Delta N_i^{st}$, where ΔN_i is the augmentation observed (at the plateau, as in Fig. 1), and ΔN_i^{st} is the augmentation expected if the contaminant were monatomic and had an ionization potential equal to I_x. The value of ΔN_i^{st}, which is interpolated from experimental measurements of ΔN_i for monatomic contaminants[2], is larger, the smaller is I_x, and is given approximately by the empirical equation:

$$\Delta N_i^{st}/N_i \approx 0{\cdot}395 + 0{\cdot}34[1-(I_x/E_0)], \text{ with } I_x < E_0$$

In the experiments on the isotope effect, ionization currents produced by β-rays (mean kinetic-energy about 18 keV) from a source of nickel-63 deposited on a gridded electrode were determined in an ionization chamber, by methods already described[8], for various concentrations of the contaminant. Normal and fully deuterated ethylene and n-butane were studied, both in neon and in argon. In Fig. 1 the observed ionization in the mixture, relative always to the corresponding values, N_i, in the pure parent gas, is plotted against the measured concentration of contaminant introduced

The curve for each deuterated hydrocarbon is consistently higher than that for the corresponding normal one by the order of magnitude of 1 per cent —about ten times the estimated error of measurement In the plateau region the ratio of these ionization currents, $(N_i + \Delta N_i^D)/(N_i + \Delta N_i^H)$, is found to be remarkably independent of contaminant concentration Mean values for the four cases are presented in Table 1

Table 1 COMPARISON OF EXPERIMENTAL AND THEORETICAL ISOTOPIC IONIZATION RATIOS

Noble gas	Contaminant	Ionization ratio, $(N_i + \Delta N_i^D)/(N_i + \Delta N_i^H)$ Experimental	Theoretical	Assumed splitting
Argon	Ethylene	1 008$_3$	1 005	$CH_2 + CH_2$
			1 026	$H + C_2H_3$
Neon	Ethylene	1 010$_2$	1 004	$CH_2 + CH_2$
			1 017	$H + C_2H_3$
Argon	*n*-Butane	1 006$_9$	1 007	$C_2H_5 + C_2H_5$
			1 030	$H + C_4H_9$
Neon	*n*-Butane	1 008$_3$	1 002	$C_2H_5 + C_2H_5$
			1 009	$H + C_4H_9$

The magnitudes of the experimental results cannot be compared with theory immediately because none of the three constants in equation (3), δ, k_2'/k_1, and M, is known However, presuming that $\delta \ll 1$, one can calculate the ionization ratio on the basis of a specific assumption regarding M This is done in Table 1 for two extreme possibilities, symmetrical cleavage, and dissociation of a hydrogen atom The calculated isotope effects are of the same order of magnitude as those observed, comparison points to symmetrical splitting with Ar* ($\bar{E}$ = 11 6 eV), and dissociation of H (or of H_2) with Ne* ($\bar{E}$ = 16 7 eV) A suggestive fact is that with Ne*, but not with Ar*, there is ample energy to dissociate an excited hydrogen atom It should be emphasized, however, that the model embodied in equation (3) may be seriously oversimplified, for either process (1) or process (2) may encompass more than a single pathway (with the former, the ion may be left in various excited states, with the latter, there may be competitive 'dissociation' pathways)

Additional conclusions are that pre-ionization in these highly excited states is relatively slow, requiring times of the order of magnitude of 10^{-13} second or longer, and that pre-ionization in molecules is not a rare phenomenon, but a prevalent one, since[2] for most molecules the excited states with E somewhat greater than I possess a large part, and often the greater part, of the total oscillator strength of the valence electrons

The results also point to the importance of similar experiments with the absorption of light It is predicted that the same isotope effect will be found in η_p Moreover since $\eta_p = \sigma_{pi}/\sigma_p$, where σ_{pi} is the cross-section for photo-ionization and σ_p is the total absorption cross-section at the same value of $E = h\nu$, the entire isotope effect is predicted to lie in σ_{pi}, and none of it in σ_p

We thank Dr Leon M Dorfman (Argonne National Laboratory) for providing the deuterated hydrocarbons, and Dr Ugo Fano (National Bureau of Standards, Washington) for discussions One of us (R L P) also thanks Prof Michel Magat (Faculté des Sciences de Paris), in whose laboratory the theoretical basis for these experiments was developed

Search for an Effect of Magnetic Fields on Electromagnetic Radiation

IT has been suggested that some anomalies in astronomical observations may involve a photon–photon interaction of the type[1]

$$\frac{\Delta\nu}{\nu} = KlU \qquad (1)$$

where K is a constant equal to 2 6 × 10^{-15}, l is the path length in cm, and U is the energy density in erg/cm^3 It has further been suggested that the Mossbauer effect might be used to provide a test of this hypothesis if the radiation could be passed through a region of high photon density such as might be obtained in the vicinity of plasma[2] Since the form of this proposed interaction does not contain any frequency-dependence and since if it were to exist it would contradict accepted electromagnetic theory, it seemed that assuming U to be the energy density due to a static electromagnetic field was not an unallowable extension of an already radical hypothesis Since a static magnetic field is not quite analogous to the original circumstances discussed in ref 1, this experiment does not fully test the hypothesis stated in equation (1) However, a magnetic field produces by far the largest electromagnetic energy density obtainable in the laboratory (this was pointed out to us by J Heberle) and thus provides a conveniently easy experiment

Accepted electromagnetic theory does not predict any change in frequency for radiation passing through a magnetic field, some scattering effects are expected to take place at very high magnetic field strengths[3]

The measurements were carried out by allowing the 14-keV γ-rays emitted by iron-57 to pass through transverse and longitudinal magnetic fields produced by permanent magnets The velocity spectrometer used will be described elsewhere[4] The source used was cobalt-57 diffused into copper The absorber was $Na_4Fe(CN)_6 \, 10H_2O$ with the iron enriched with iron-57 This combination produced a single absorption line approximately 45 per cent deep (without background corrections) and 0 5 mm/sec wide

In the transverse case, the magnetic field was 5,500 œ at the centre of the gap traversed by the γ-radiation and fell off to half this value in about 0 5 in from the centre From equation (1), this would give a frequency shift of about 5 × 10^{-9} The measurements with the magnetic field along the direction of the photons were performed by providing a horseshoe magnet with pole pieces pierced by a hole 0 75 in in diameter This allowed radiation to go through one pole piece, cross the gap in a direction parallel to the magnetic field, and emerge through the hole in the other pole piece The field in the gap of this magnet was 1,700 œ and the calculated effect was about 5×10^{-10} Along this longitudinal path, the magnetic field in the gap was in the direction of propagation of the photons but was oppositely directed outside the magnet Hence the line integral of the field along the path was zero To allow for the possibility of a directional effect, the experiment was also repeated with the source placed in the field-free region inside the hole in one pole tip The effect calculated from equation (1) in this case was 5×10^{-11}

The results obtained from the velocity spectrometer were analysed by a least-squares programme The principal source of error in the measurement was from counting statistics This error was increased to allow for systematic errors such as temperature fluctuations within the instrument The results are shown in Table 1 It is clear there is no effect of a magnitude comparable with that expected from equation (1) This is not at all surprising The interpretation of the evidence supporting equation (1) has been seriously questioned by several authors[5], one of whom suggested that such an effect might be present but that K should be only a thousandth of the value given here[6] It is clear that we have not observed even this diminished effect It must also be made clear that our measurement does not really constitute a full test of equation (1) anyway since this experiment was done with a static magnetic field instead of a radiation field On the other hand, to our knowledge there have been no previous measurements in which the influence of magnetic fields on the frequency of photons has been tested to such accuracy (An experiment was performed by Banwell and Farr[7] to see if the velocity of light was unchanged in a transverse magnetic field They allowed one arm of an interferometer to pass through a region of 20,000 œ for 1 m If there had been a frequency shift of the type looked for in the present work, it would also have been observed in these measurements In terms of equation (1), the limit that can be set from these early results is about three orders of magnitude larger than that we can set from the first result in Table 1)

Table 1 SUMMARY OF RESULTS

Type of field	Measured effect $\left(\frac{\Delta\nu}{\nu}\right)$	Effect calculated from equation (1)
Transverse	$(2 \pm 4) \times 10^{-15}$	-5×10^{-9}
Longitudinal $\left(\int \vec{B}\ \vec{ds} = 0\right)$	$(1 \pm 5) \times 10^{-15}$	-5×10^{-10}
Longitudinal $\left(\int \vec{B}\ \vec{ds} \neq 0\right)$	$(1 \pm 4) \times 10^{-15}$	-5×10^{-11}

Our results can stand on this ground alone, without reference to any theoretical expectation The third result given in Table 1 may also be interpreted as showing that the net magnetic charge on the photon is less than 3×10^{-26} e m u The experiment could be repeated with at least 10-fold greater accuracy by using techniques developed for measuring the gravitational red shift Further increase in accuracy could be obtained by the use of electromagnets which can produce considerably stronger magnetic fields

We thank Dr M R Perlow for preparing the enriched absorber

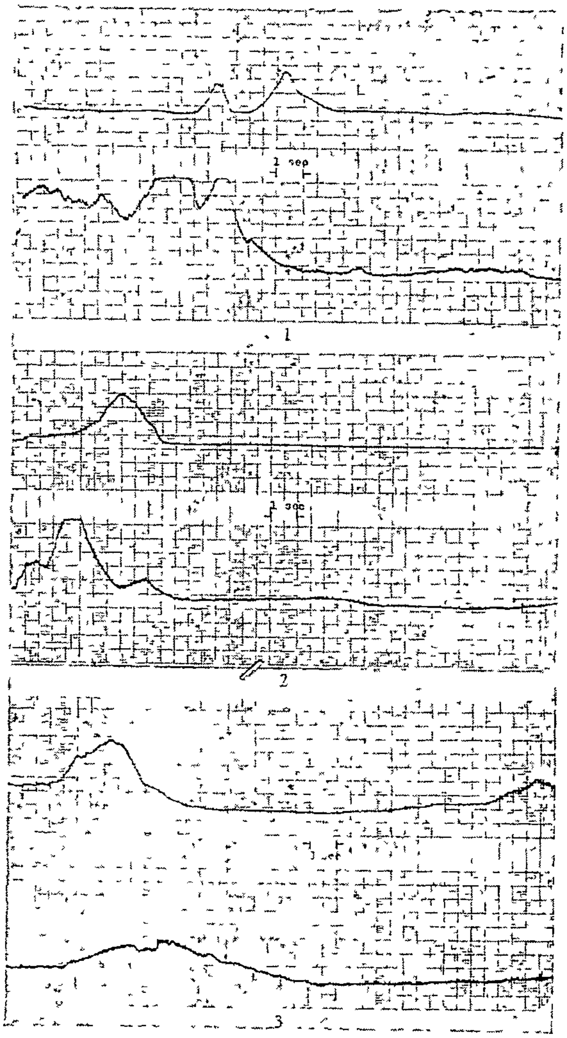
Photoelectric Tracking of Instantaneous Motions in Aurora

EXTENSIVE work done[1–6] on auroral drift motions is essentially based on the all-sky camera records The speeds so obtained range from 0 05 km /sec to 2 2 km /



1
2
3

Figs. 1–3 Recordings from intense and moving auroral bands on different nights Time increases from left to right and each big vertical division is one-half sec The time-delay between corresponding signal events is seen to vary sec Fast photographic techniques have also been used[7] to get short-term velocities of the order of 2 5 km /sec This communication is to present some cases of instantaneous motions recorded photoelectrically and confirmed by simultaneous visual observations The device is a double photometer system used earlier[8–9] collecting light from two fields each 0 55° in size and separated from each other by 3° Observations were made separately for two orientations of the field-pair, one at 90° to the other Signals were recorded using a two-channel Sanborn recorder at a chart speed of 10 mm /sec

Figs 1–3 show signals from bright moving bands as visually observed at the time of recording The intensity in each case was easily about 100 kilo rayleighs or more A time-lag is seen in one of the two channels between corresponding signal events This time-delay, which is indicative of motion of the auroral form across the two fields of view, seems to vary from 1 5 to 2 5 sec The delay may be seen in any one of the two channels This is perhaps a matter of speed and direction at transit across the two fields Assuming the auroral height as 100 km the speeds obtained range from 4 to 10 km /sec These are, however, components in the direction of motion Furthermore, only when the orientation of the field-pair is in the direction of motion of the auroral form could this kind of a time-delay in one channel be seen

The double-peak feature in Fig 1 with a drop in the signal level in between in each channel is intriguing Probably, this could be due to two independent auroral patches moving in succession The widths of the peaks in one channel seem to be reversed relative to those in the other The moving form may not be steady in speed, size or intensity during its passage across a field of view, particularly so across two fields of view

The high speeds mentioned here obtained over a few seconds could perhaps be distinguished from the usual drift motions observed from all-sky records Dzhordzhio in the U S S R has obtained[10] by photoelectric methods speeds of the order of 9 km /sec and mentions also speeds of 3–4 km /sec by visual estimates due to Galperin

Temperature Coefficient of Electrical Resistance of High-Purity Rhodium

I SUPPORT Price and Taylor[1] in believing that the temperature coefficient of resistance of rhodium is appreciably higher than 0 00457, the maximum value hitherto recorded in the literature

As long ago as 1936, measurements made by the National Physical Laboratory on a sample of rhodium specially purified in our refineries indicated a value of 0 00463, confirming exactly the higher value now quoted by the above authors, and since then this value has been widely used in our own organization

It is to be hoped that the higher value will now be generally recognized

Sputtered III–V Intermetallic Films

In the course of investigating methods for the deposition of films of semi-conductive materials, it was found that the antimonides of indium and gallium can be readily deposited by means of cathodic sputtering Reactive sputtering has been widely used for several decades for formation of films of oxides and certain other compounds[1], but there seems to have been little interest in the direct sputtering of compound materials Kane and Wood attempted to produce a sputtered film of Ag_2Te, but obtained rather $Ag_{2-x}Te$ (ref 2) Recently, work concerned with sputtering yields for gallium antimonide[3] and directional patterns formed by sputtering from single crystal balls of indium antimonide has been reported[4], but in neither case were properties of the films discussed

The apparatus used was similar to that described by Belser and Hicklin[5] The substrate holder was adjustable in height relative to the suspended source and fitted with a small tantalum wire heater for controlling the temperature of the substrates Films were deposited on 1-in ^{2} substrates of fused silica or an aluminosilicate glass (Code 1723, Corning Glass Works) Prior to deposition, the substrates were thoroughly degassed in vacuum (about 10^{-5} mm mercury) at elevated temperatures The system was purged with dry argon (99 996 per cent minimum purity), which was also used as the bombarding gas for sputtering Pressures during sputtering were in the range of approximately 50–150μ mercury Sputtering was carried out at potentials of 2–4 kV

and for periods of up to about 1 h Following deposition, the films were normally annealed at the deposition temperatures for about 30 min Samples of source materials were in the form of undoped polycrystalline slices, with exposed surface areas of some 2–6 cm^2 Two samples of each material, obtained from different suppliers, were used

Results of the measurements of room temperature electrical properties of the indium antimonide and gallium antimonide films are presented in Table 1 Substrate temperature is seen to have an important effect on mobility Films deposited at the lower temperatures, below 100° for InSb and below about 300° for GaSb, were characterized by large values of resistivity and by mobilities below the measurable limit (approximately 1 cm^2/V-sec), GaSb 13, which was deposited at 320°, was anomalous in this respect, having an immeasurably small mobility Increasing temperature in general led to lower resistivities and higher mobilities, but film thickness also appears to have had an effect on these properties Higher values of the mobility can undoubtedly be obtained through investigations into the proper conditions for deposition and annealing The resistivities of the films deposited at the highest temperatures were frequently lower than those of the source materials In every case, the carrier type, as determined from Hall or thermoelectric probe measurements, was the same for the film as for the source

All the films reported here were metallic in appearance The compound characters of the higher temperature films were confirmed by means of X-ray diffraction Films deposited at the lowest temperatures (InSb 13, deposited at 50° C, and GaSb 9 and 10, deposited at 60° and 110°, respectively) gave no diffraction peaks, and were presumably amorphous

Diffraction patterns of the first films produced (InSb 2, 5, 6 and GaSb 1 and 2) showed the presence of oxides—Ga_2O_3, In_2O_3, and in certain instances possibly Sb_2O_3—in addition to the intermetallic compounds as major phases However, more careful purging of the chamber with argon, ion bombardment cleaning of the surface of the sources, and minor modifications to the chamber fittings have served to reduce the level of residual air in the system to the point where no indications of oxides were then discernible in the diffraction patterns

Study of the formation of the intermetallic compound films by this process will perhaps throw some light on the mechanism of sputtering If material transfer were atomic, that is, if antimony and indium or gallium sputter independently, combination of the deposited atoms to reform the intermetallic compounds on the substrates would not be expected at low substrate temperatures The diffraction evidence for the low-temperature, amorphous films is inconclusive, but it may be significant that there were no indications of the elemental materials Further, considerable fractionation of the dissociated compounds, as a result of the large differences in vapour pressures of antimony and the metallic constituents, would be expected if the older sputtering theory of localized heating and subsequent evaporation were valid No appreciable degree of fractionation occurred in the experiments reported here It might, therefore, be presumed that the intermetallic compounds sputter molecularly, or perhaps as polyatomic aggregates Extension of these investigations to other III–V compounds should help to clarify these points

I thank W A Gutierrez and R S Smith for the Hall effect measurements, Dr H deSchmertzing for the diffraction analyses and Dr C Feldman for advice

OCEANOGRAPHY

Abnormal Hydrographical Conditions in the Menai Straits

RECORDS of the temperature and salinity of the water passing through the Menai Straits have been maintained in this laboratory for several years Samples for salinity determinations are taken regularly at the end of Menai Bridge pier All the evidence available suggests that samples taken at this point are truly representative of the main water mass in the Straits at the time Table 1 shows the monthly mean salinities recorded over a period of six years (1955–60) together with the records for the first eight months of 1961

The monthly means have been calculated from the results of regular samples taken at a fixed time at 7-day intervals It is apparent that although the mean salinity for January 1961 was quite typical of the values observed for this month during the previous six years the mean value for February 1961 was exceptionally high These unusually high salinities persisted until August although the magnitude of the anomaly tended to decrease from March onwards

In coastal waters exceptional conditions such as these might be very localized However, the total rainfall for the first eight months of 1961 as recorded at Valley Anglesey was 2 8 in above the mean total rainfall recorded at this Station for the corresponding periods during the years 1955–60 One would expect, therefore that any effect of local run-off would be to produce a negative salinity anomaly during the period in question

Furthermore, the sea-water temperature records for the Menai Straits and the air temperature records at Valley show a strikingly similar anomaly to the salinity records (Fig 1)

Table 1 MONTHLY MEAN SALINITY (PARTS PER THOUSAND) AT MENAI BRIDGE

	Mean	Jan	Feb	Mar	April	May	June	July	Aug	Sept	Oct	Nov	Dec
1955 to 1960	Mean of the Monthly means	32 44	32 37	32 46	32 64	32 74	32 84	32 73	32 69	32 53	32 47	32 31	32 44

1961	Monthly mean	32 45	33 78	34 01	33 64	33 82	33 80	33 63	33 19				

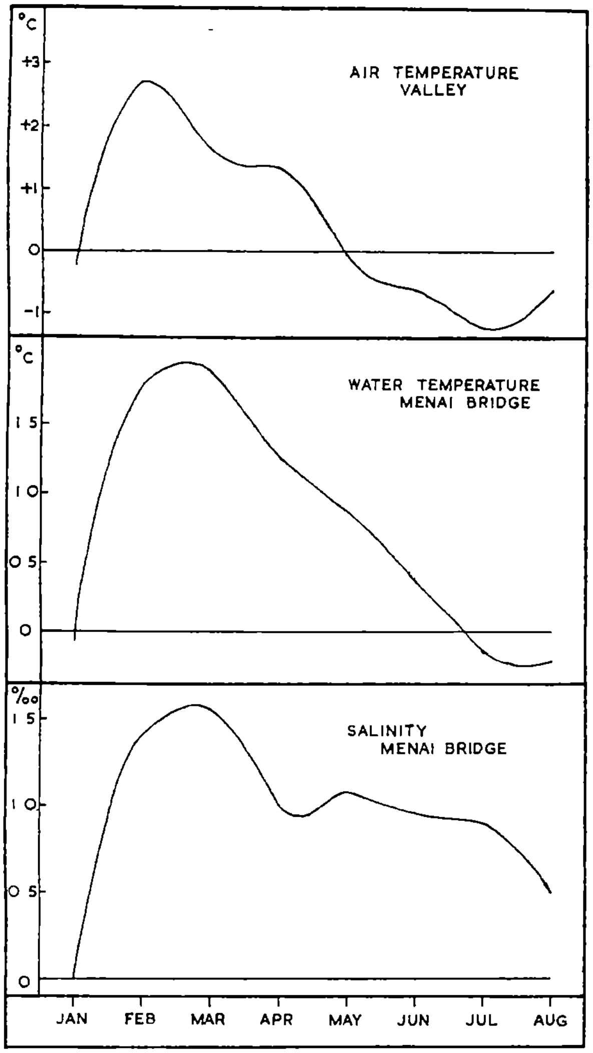

Fig 1 Monthly means for 1961 expressed as anomalies from the mean of the corresponding monthly means for the years 1955–60

It seems possible that the high salinities recorded at Menai Bridge during the early part of 1961 were in fact the result of an unusually strong incursion of Atlantic water into the Irish Sea The temperature records are suggestive of this incursion being the result of a sudden change in either or both the strength and direction of the Gulf Stream System A change in the oceanic circulation may have caused marked salinity and temperature anomalies only in limited parts of the Irish Sea such as the Menai Straits On the other hand it may have been much more widespread in its effects This will only become clear when the appropriate hydrographical data from a much wider area obtained by other laboratories become available In addition, it is to be expected that the faunistic records for the Irish Sea and associated waters for the period in question will provide additional evidence of any major change in the oceanic circulation which occurred

We thank the Director General of the Meteorological Office for supplying the meteorological data

CHEMISTRY

Dynamic Contact Angles and Rates of Adsorption

Several published papers have indicated that the contact angle varies with the velocity with which a fluid/fluid interface moves, or is caused to move, along a solid surface[1–6] In particular, Ablett's results suggest that, under his experimental conditions, hysteresis is absent when the advancing angles, which increase with interfacial velocity, and receding angles which decrease, are extrapolated to zero velocity

We have devised a method whereby a bubble of one fluid can be caused to grow with a constant radial velocity between parallel plates, displacing a second fluid This process can be reversed, affording a means for measuring advancing and receding angles as a function of the interfacial velocity

A typical set of results is shown in Fig 1 for water displacing air, saturated with water vapour, between siliconed glass surfaces The receding angles, which are much more difficult to reproduce at the higher speeds, are also shown The values at zero velocity were obtained by the 'sliding drop' method[7]

It is clear that hysteresis is present, as is shown by the difference between the advancing and receding angles at interfacial velocities below 1 mm/min Below this speed, the angles are independent of velocity within the limits of experimental error (± 1°), confirming Yarnold and Mason's observations

Above this speed, the advancing contact angle increases linearly with the growth velocity up to about 4 mm/min At higher speeds, the rate of change diminishes until finally a limiting value is reached at about 8 mm/min The receding angle also varies linearly with the interfacial velocity above 1 mm/min This dependence is of the same form as that found by Ablett We believe that the absence of hysteresis in his system, and his ability to study receding angles at higher speeds than those reported here, were the results of water having penetrated the solid surface Our receding angles were always determined after the water had been in contact with the solid surface for 45 min

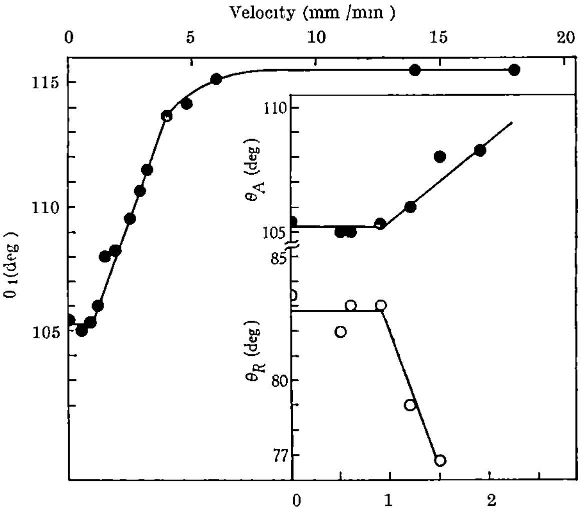

Fig 1 Advancing contact angles (θ_A, solid circles) as a function of the velocity of an air/water interface moving along a siliconed glass surface Inset Advancing and receding angles (θ_A, open circles) at low interfacial velocities Temperature, 22° C

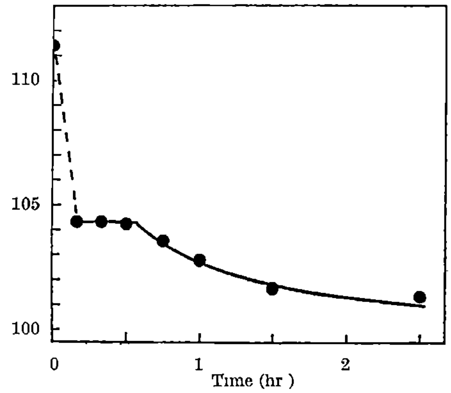

Fig 2 Relaxation of θ_A after halting an interface advancing at 3 mm /min Temperature, 22° C

Following Hansen and Miotto[8], we attribute the absence of a velocity effect at low speeds to the impressed velocity V being smaller than the natural displacement velocity V_N of the peripheral three-phase line of contact V_N is given by l/τ, where l is the peripheral thickness and τ is the relaxation time for water molecules in this periphery When $V \gg V_N$, the molecules are disorientated at the line of contact, and the corresponding boundary tensions will be displaced from their equilibrium values

Since the velocity effect is not observable for low radial growth velocities, we may set V_N as greater than 1 mm /min , or 2×10^{-3} cm /sec With l of molecular dimensions, τ is less than 10^{-5} sec Bockris, Mehl, Conway and Young[9] find the mean relaxation time for water molecules at the copper/water interface to be about 10^{-6} sec , intermediate between the values for bulk water (10^{-10} sec) and ice (10^{-3} sec) A shorter time would be expected at the siliconed glass water interface, and 10^{-5} sec is certainly an overestimate

If the interface is caused to advance over the surface with a velocity greater than 1 mm /min and the impressed drive is then cut off, the contact angle relaxes back rapidly to a value which is within 1° of the low velocity (or static) contact angle After differing periods, about 15 min in the case shown in Fig 2, the angle begins to decrease as the liquid penetrates the solid surface This process has been followed for periods up to 18 hr , and is roughly exponential

Similar results have been obtained when the siliconed glass plates were replaced by polyethylene plates, and when the air phase was replaced by a liquid hydrocarbon, suggesting that the technique could be used for following rates of adsorption at solid/fluid interfaces Fuller details will be reported on completion of these studies

These investigations were financially supported by the Iraq Petroleum Co , Ltd

Production of Vibrationally Excited Species from the Photolysis of Nitroso Compounds

There have been a number of recent investigations on the production of vibrationally excited species by the method of flash photolysis[1-5] with particular reference to two possible mechanisms, direct vibrational excitation or the initial formation of an electronically excited state the energy of which is then reorganized internally Basco and Norrish[1] have concluded that vibrationally excited nitric oxide was produced directly on photolysing nitrosyl chloride, whereas Symons and Yarwood[4,5] have interpreted their observation of the production of CCl radicals in the photolysis of a number of halogenated methanes in terms of the formation of an electronically excited substituted methyl radical the energy of which was internally converted into vibration Experiments have been carried out on the flash photolysis of trichloronitrosomethane (CCl_3NO) in an attempt to determine the fraction of energy appearing as vibration in each fragment produced on photolysis and to attempt to determine which of the two possible mechanisms is operative in this case A new transient spectrum resulting from the photolysis of this molecule is also reported

Absorption spectra were taken at known delays after the photoflash discharge by means of a second, spectroscopic flash lamp[6] controlled by an electronic delay unit Experiments utilizing a two-path vessel[7] indicated that the reciprocity relationship was found to hold for the absorption of the CCl radical and enabled the peak height resulting from the microdensitometer trace of its spectrum to be taken as a direct measure of relative concentration

The photolysis of CCl_3NO under adiabatic conditions in which no inert gas was added as coolant resulted in the production of CN and NO in high states of vibrational and rotational excitation, indicative of the high temperature reached A large number of mixtures of CCl_3NO and argon, suitably chosen for convenient temperature variation, were investigated for a series of delays throughout the complete spectral range (2150–5600 Å), no transient spectrum which might have been due to the production of a maximum free radical concentration at some optimum temperature was observed The experiments described here were carried out under isothermal conditions which were obtained by mixing the reactant with high pressures of inert gas, in this case either nitrogen or argon

The CCl radical concentration as observed by the transition ($^2\Delta - {}^2\pi$) (ref 8) was found to be dependent on the first power of the photoflash intensity and decayed by means of a first-order process, though measurements were made only in the duration of the flash The (0,0) transition of the γ system of nitric oxide was observed at the shortest delay (Fig 1), the (0,1) transition being extremely weak if present at all This provides good evidence for the first step as

$$CCl_3NO + h\nu = CCl_3 + NO$$

rather than

$$CCl_3NO + h\nu = CCl_2 + NOCl$$

as the nitrosyl chloride would have been further photolysed to nitric oxide in a highly vibrationally excited state[1] The position of the upper limit of the absorption peak in the visible (~ 6800 Å), which has been shown to be diffuse (Thrush, B A , private communication), corresponds to a bond dissocia-

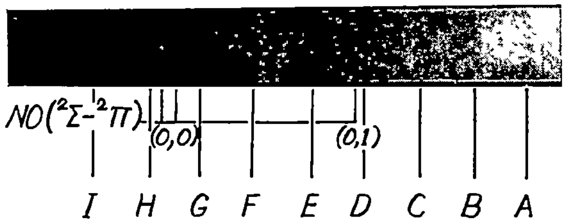

Fig 1 Flash photolysis of trichloronitrosomethane under isothermal conditions $P_{\mathrm{CCl_3NO}}$ = 0 5 mm , $P_{\mathrm{N_2}}$ = 500 mm , E = 2,500 Joules, t = 2 7 μsec

tion energy of $\leqslant$ 42 k cal mole^{-1}, giving rise to the decomposition of this molecule to a white solid The lower limit of the photoflash output (~ 1900 Å) corresponds to an energy of 150 k cal mole^{-1} It can be concluded that nearly all the excess energy above the dissociation energy must appear as vibration in the substituted methyl radical as the unimolecular reaction

$$CCl_3 = CCl + Cl_2$$

is endothermic to the extent of 107 k cal mole^{-1}. This result is similar to that observed on the photolysis of halogenated methanes[4,5] Preliminary experiments on the photolysis of CF_3NO resulted in the observation of the spectrum of nitric oxide in its electronic and vibrational ground state and is in agreement with the work of Hazeldine and co-workers[9], but CF was not observed This may be due to the fast reaction of any CF_3 produced with the parent molecule

Table 1 Spectrum *A–I*

Band	λ_{air} (Å)	v_{vac} (cm^{-1})	Δv_{vac} (cm^{-1})

I	2233 0	44,970	

A series of regularly spaced diffuse bands (Table 1) not previously reported were observed (*A–I*, Fig 1) The simplicity of the spectrum suggests that the carrier is diatomic The spectrum followed the CCl($^2\Delta$ − $^2\pi$) transition and the separation of the bands is comparable with, though significantly less than, the fundamental frequency of CCl in the ground state (846 cm $^{-1}$) (ref 10) By analogy with other iso-electronic systems such as CF and NO (ref 10), where the vibrational frequency of the excited $^2\Sigma$ state is significantly greater than that of the ground state, it is suggested that the upper state is a $^2\pi$ state rather than a $^2\Sigma$ state It is noted that the spectrum lies above the limit of dissociation to normal products.

The direct production of vibrationally excited substituted methyl radicals cannot be explained by treating the system as an impulse problem in terms of the proportion of the excess energy appearing in the radical, though there is no reason why the molecule can be so considered The initial formation of an electronically excited CCl_3 radical also appears unlikely as the lowest lying antibonding electronically excited state would require high energy to be reached[11] Walsh[11] has indicated that a 25 electron system of formula AB_3 would be tetrahedral, though the structure of no such system has, as yet, been reported and the part played by a possible change in shape is uncertain The group attached to the substituted methyl radical, whether it be a halogen atom, a nitro group[4,5] or a nitroso group, appears to have little effect on the fraction of energy appearing as vibration in the substituted methyl radical

I thank Prof R G W Norrish for his advice and encouragement throughout the course of this work

A Reproducible Magnesium Oxide Standard for Reflectance Measurement from 0·3 to 2·6μ

The reflectance standard for colorimetric purposes adopted by the Commission Internationale de l'Eclairage in 1931 is a bed of magnesium oxide deposited from the smoke of magnesium ribbon or turnings burning in air As a standard it suffers from various defects and in spite of subsequent attempts to stipulate more closely the conditions to be observed in its preparation variations of 1 or 2 per cent can occur in the reflectance factor as measured in the visual spectral range[1] Alternative materials such as barium sulphate[2] have proved no better than magnesium oxide as reference standards The difficulties are enhanced if the standard is required to be applicable over a wider wave-length range, for example 0 3–2 6μ At some time in the future a theoretical perfect diffuser will be adopted as reference (C I E recommendations, 1959) but at present there is no practical alternative to magnesium oxide

The purpose of this note is (1) to describe briefly an improved electrostatic precipitation process which can be used to produce standards indistinguishable in reflectivity over the spectral range 0 3–2 6μ when they are examined in a Beckman *DK*2 ratio-recording spectrophotometer with an integrating sphere attachment, (2) to give some results on the effect of changes in the density of packing of magnesium oxide beds on their reflectance and to indicate their relevance to the choice of conditions for preparing standards from powder materials

Electrostatic deposition of magnesium oxide is carried out on each of a pair of flat silver disks previously polished to match in reflectance at 0 5μ and then fitted into aluminium cylinders to form cups 2 mm deep Each disk in turn is held facing downwards at an angle of 45° to the vertical and maintained at a voltage of between 6 and 10 kV with reference to an earthed electrode with a sharply pointed end 5–8 cm distant from the disk so that a brush discharge takes place without sparking Burning magnesium ribbon is held in an earthed holder below the pointed electrode so that the smoke from the uprushing convexion current is diverted by the electric field and deposited on the silver surface At intervals the beds of powder are compared with one another, and also separately with an opal glass tile, for reflectance over

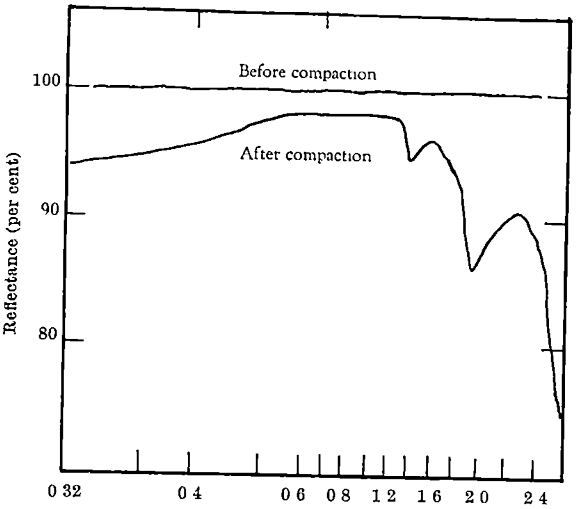

Fig 1 The effect of a change in apparent density from 8 7 to 30 per cent v/v on the reflectance of a standard prepared from magnesium oxide smoke

the whole wave-length range Further deposition is carried out until the beds show equal reflectance and the relative reflectance of the opal glass shows a minimum value at every point in the range The depth of bed required to attain these results lies between 1 7 and 2 0 mm Such standards can be used in dry dust-free conditions for about two weeks before replacements are necessary Beds prepared at different times over a long period have given the same values for a carefully preserved and cleaned opal glass tile, indicating that the method of preparation is highly reproducible

The effect of compacting such a bed under a pressure of 1,000 lb /in ^{2}, which changes the initial apparent density of 8 7 per cent v/v to about 30 per cent v/v, is shown in Fig 1 There is a marked loss of reflectance in the ultra-violet and near infra-red regions The specific absorption bands at 1 4 and 1 9μ, which are probably due to water[3] present as moisture in the original powder bed, become noticeable when the absorption to scattering ratio changes on compaction of the bed

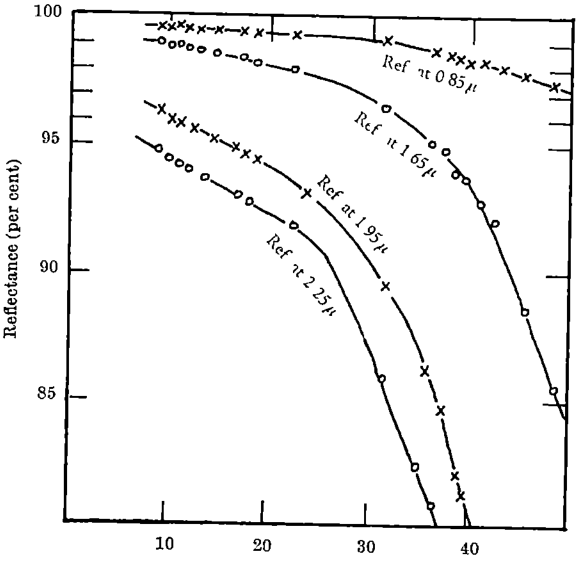

Fig 2 The effect of changes in apparent density on the reflectance at various wave-lengths of a thick bed of magnesium oxide powder having a maximum particle size of 1 0μ

Changes of reflectance with apparent density were studied with beds of light magnesium oxide (analytical reagent grade) of particle size under 1μ The rate of change of reflectance with density (Fig 2) is slow in the density range associated with the high bulkiness of small particle size powders[4] and increases rapidly as close-packing particle-to-void ratios are approached

With reflectance standards based on powder beds highest reflectance coupled with the slowest rate of change of reflectance with density is desirable The results given here show that this condition corresponds with low apparent density and can be obtained by the electrostatic technique described

Oxygen Effect as an Explanation of Differences between the Action of α-Particles and X- or γ-Rays on Aqueous Solutions of Amino-acids and Proteins

Alexander and Rosen, working with oxygen-free aqueous solutions of tryptophan and other substances, have discovered certain differences between the action of α-particles and of X-rays[1] They have also found such effects with proteins[2] In the case of aqueous solutions of benzene, the greater effectiveness of α-particles compared with X-rays in causing ring splitting (under oxygen-free conditions) is probably associated with the fact that the α-particles are producing relatively large amounts of oxygen simultaneously with free radicals, so that α-irradiation in the absence of added oxygen resembles X- or γ-irradiation in the presence of oxygen[3] This explanation superseded a previous view that the α-particles were producing some more specific effect The irradiation of tryptophan resembles that of benzene in that tryptophan undergoes ring splitting to formylkynurenine on X-irradiation in the presence of oxygen, but not in the absence of oxygen[4], suggesting that an oxygen effect (or perhaps a hydrogen peroxide effect) might explain Alexander and Rosen's results It would then be unnecessary to postulate the formation of activated hydrogen peroxide by α-particles In order to obtain further evidence on this question, we have studied further the effect of oxygen on the γ-irradiation of aqueous tryptophan

Fig 1 shows the difference in extinction coefficient between the irradiated and unirradiated solutions for 2 × 10^{-4} *M* tryptophan irradiated with γ-rays (66,400 rads) in the absence of air, in the presence of air, and in the presence of 10^{-3} *M* hydrogen peroxide (air absent), Our results with γ-rays in the absence of oxygen are in reasonable agreement with Alexander and Rosen's results with X-rays under nitrogen, considering the smallness of the change produced (the loss in absorption at 279 mμ is about 1 5 per cent)

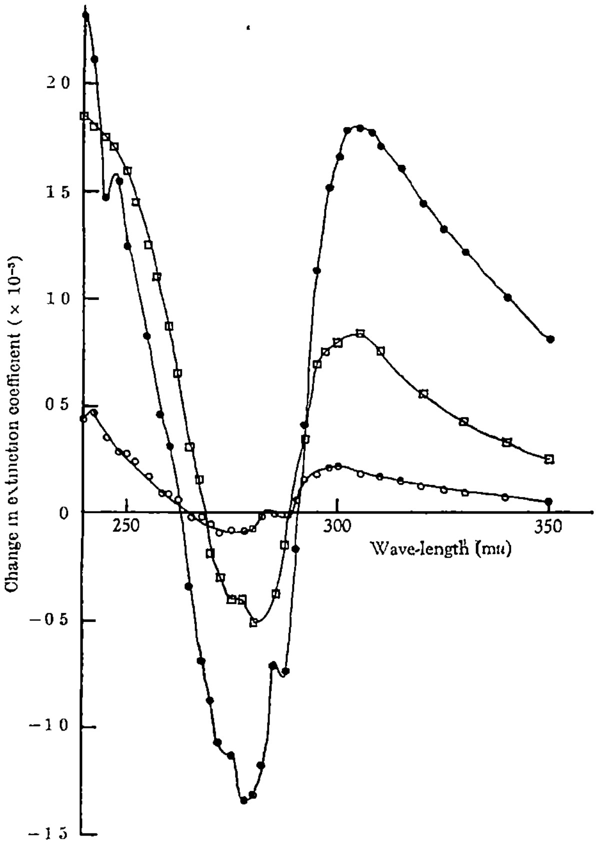

Fig. 1. Difference between extinction of γ-irradiated tryptophan (2×10^{-4} *M*) and unirradiated tryptophan. ○, irradiated in absence of air and hydrogen peroxide; ●, irradiated in presence of air; ☐, irradiated in presence of H_2O_2 (10^{-3} *M*)

Our results with γ-rays in the presence of oxygen or hydrogen peroxide show similar qualitative features to Alexander and Rosen's results with α-particles under nitrogen, that is, compared with the result of X- or γ-irradiation in the absence of oxygen, they show a larger drop in extinction coefficient near the tryptophan absorption peaks at 279 and 287 mμ, a larger rise below about 270 mμ, and an increased production of a substance or substances absorbing above 300 mμ. This observation suggests that the α-particles are indeed acting through the formation of oxygen and/or hydrogen peroxide from the water, simultaneously with free radicals. It should be noted also that previous work on the α-irradiation of aqueous solutions has also been interpreted in such terms[5,6].

We have measured the loss of tryptophan by a method described by Spies and Chambers[7]. Results are shown in Fig. 2. For γ-irradiation in the absence of air, the initial yield for loss of tryptophan was *G* = 1·2, in fair agreement with Alexander and Rosen's result for X-irradiation in the absence of air of *G* = 0·92[1]. Dissolved air increased the initial yield with γ-rays to *G* = 2·0. The yield with α-particles in the absence of oxygen was *G* = 1·8[1]. It is somewhat surprising that the α-particle yield should be so much more than the yield with X- or γ-rays in the absence of oxygen, since although the formation of oxygen and/or hydrogen peroxide would be expected to enhance the yield, radical production with α-particles is less than a fifth of that with X- or γ-rays. Perhaps a short chain reaction involving hydrogen peroxide occurs during α-irradiation. Ribonuclease (0·1 per cent) protects tryptophan (2×10^{-4} *M*) against radiation[1]. Alexander and Rosen found that ribonuclease reduced the yield for destruction of tryptophan by X-rays to 35 per cent of its value in the absence of ribonuclease, and the yield for destruction by α-particles to 63 per cent[2]. We have found a reduction to 50–60 per cent for γ-irradiation both in the absence and in the presence of air. The poor agreement between Alexander and Rosen's result with X-rays and our result with γ-rays makes it difficult to draw conclusions from these results.

The ammonia yield from γ-irradiated tryptophan (2×10^{-4} *M*) has been measured using Nessler's reagent. The yield is linear up to about 30,000 rads both in the absence and in the presence of air. The initial yield in the absence of air was *G* = 1·3 compared with *G* = 1·8 found for X-rays in the absence of air by Alexander and Rosen. Our initial yield for γ-rays in the presence of air was *G* = 6·8. Alexander and Rosen found *G* = 1·8 for α-irradiation in the absence of air. We suggest that this yield is qualitatively consistent with the decreased yield of radicals produced by α-particles compared with X- or γ-rays, coupled with the enhancing effect of the oxygen and/or hydrogen peroxide simultaneously produced.

Alexander and Rosen report that oxygen produced less than 5 per cent change in the α-irradiation of aqueous serum albumin, as determined by the change in ultra-violet absorption[2]. This would be expected if the α-particles produce their own oxygen and/or hydrogen peroxide. They state that oxygen produced less than 25 per cent change in the effect of X-irradiation. This would be consistent with a fairly large increase in true ultra-violet absorption due to an oxygen effect counterbalanced by a decrease in that part of the absorption which is due to light-scattering, the overall effect of X-irradiation in the presence of oxygen being qualitatively similar to, but quantitatively greater than, the effect of α-irradiation whether in the presence or absence of oxygen.

We conclude that the effects of α-particles on amino-acids and proteins in aqueous solutions can be interpreted in terms of the simultaneous production of free radicals and of oxygen and/or hydrogen peroxide from the water. If this view is correct, then oxygen or hydrogen peroxide would be expected to have a more important influence on details of the X- or

N-H Stretching Frequencies of Amines and Amides

Bellamy and Williams[1] found that for primary amines in which both N–H bonds are equivalent and mass and coupling effects negligible, the symmetric (ν_s) and asymmetric (ν_{as}) NH_2 stretching frequencies were related by equation (1) with a standard deviation of 4.8 cm⁻¹ and in the more restricted case of *meta* and *para* substituted anilines, Krueger and Thompson[2] found that equation (2) was obeyed with an average error of less than 1 cm⁻¹.

$$\nu_s = 0.876\,\nu_{as} + 345.5 \qquad (1)$$

$$\nu_s = 0.682\,\nu_{as} + 1{,}023 \qquad (2)$$

For primary amides, Puranik and Ramiah[3] deduced the following equation.

$$\nu_s = 1.1214\,\nu_{as} - 542.5 \qquad (3)$$

Krueger[4] has recently interpreted the lower slope of the aniline correlation (2) as opposed to the general amine correlation (1) and amide correlation (3) and the fact that the line relating ν_s and ν_{as} given by equation (3) is displaced from equation (2) as evidence for a systematic change of sp^3/sp^2 character of the amino-group in the aniline series as the electron withdrawing or donating power of the substituent alters. However, the displacement of line (3) is probably related to a dipolar field effect on the N–H bond which is *cis* to the carbonyl group[5]. For example, many secondary amides exhibit rotational isomerism and the N–H stretching bands are characteristically different[6] (*cis* amides, 3,420–3,440 cm⁻¹, *trans* amides, 3,440–3,460 cm⁻¹). Although steric effects may contribute to this shift in some compounds by a change in planarity and consequent change in resonance effect, this factor is not likely to be large where one of the groups is small. For example, formanilide[7] shows two N–H absorptions separated by 26 cm⁻¹, and for a typical value of ν_{as} (3,500 cm⁻¹) the displacement between ν_s in equations (2) and (3) is 27.6 cm⁻¹. Although the agreement may be to some extent fortuitous, unambiguous evidence[8] for the non-equivalence of the N–H bonds in primary amides is provided by the spectra of partially deuterated amides which show two N–H stretching bands 20–30 cm⁻¹ apart due to the NHD group, arising from the *cis* and *trans* relationship of the N–H bond to the carbonyl group. Steric effects could not account for this difference. A similar *cis-trans* isomerism of NHD groups has already been shown for *intra*molecularly hydrogen bonded amines[5,9]. Part of the change in slope for amides may arise from the variation of this interaction due to changes in polarity of the C = O bond.

The change in sp^2/sp^3 character in substituted anilines which Krueger deduces from the change in slope of equations (1) and (2) is more clearly evident from the N–H stretching frequencies of aliphatic and aromatic amines[10]. For example, pyrrole shows an N–H stretching band at 3,490 cm⁻¹ and in this case the nitrogen σ-bonds are close to planar (sp^2 hybridized). Secondary aliphatic amines show bands near 3,350 cm⁻¹ (in which the nitrogen is almost certainly sp^3 hybridized) and aromatic amines near 3,430 cm⁻¹ in which the nitrogen hybridization is intermediate. Similar values are obtained for primary amines if the means of ν_{as} and ν_s are taken[11]. The large shift in N–H stretching frequency between amines in which the nitrogen atom is sp^2 and sp^3 hybridized (about 140 cm⁻¹) is similar to that observed between the C–H stretching frequencies of saturated and unsaturated hydrocarbons (sp^2 and sp^3 hybridized carbon atoms, about 130 cm⁻¹)[12]. A systematic change in sp^2/sp^3 character in aniline derivatives cannot alone, therefore, account for the change in slope as the large changes in N–H stretching frequencies in the general amine correlation (1) are already due to a change in sp^2/sp^3 character.

Krueger also suggests that *ortho* substituents involving strong hydrogen bonds appear to lead to planar molecules in which the HNH bond angle may exceed 120°, for example, *ortho*-nitroaniline, 121.7°, and ethylanthranilate, 123.6°. Similar calculations for other hydrogen bonded systems such as 1-amino-anthraquinone[5] (138.2°) and 1-phenylazo-2-naphthylamine[9] (ν_{as} = 3,478 cm⁻¹, ν_s = 3,230 cm⁻¹, HNH bond angle insoluble) leads to the conclusion that the equations of Linnett[13] are inapplicable where the two N–H bonds are non-equivalent. Little reliance can, therefore, be placed on the calculations of bond angles where intramolecular hydrogen bonding occurs. It has already been shown, however, that good evidence for the planarity or near planarity of the amino group in many intramolecularly hydrogen bonded compounds is provided by the *trans* N–H stretching frequency of the NHD group in the monodeuterated derivative[5,9].

I thank the Royal Commissioners for the Exhibition of 1851 for the award of a scholarship.

Evaluation of Gel-Filtration Media by Polymer Fractionation

GEL filtration is being examined as a possible method of fractionating polymers (for example, polystyrene) which dissolve in non-aqueous solvents. The gels used with water-soluble compounds (for example, starch[1] and cross-linked dextrans[2]) are not suitable for use in non-aqueous solvents, and a major part of the research has been concerned with the evaluation of other materials.

The exact mechanism of gel filtration is not clearly understood, but it appears to be a type of molecular sieving in which solute molecules penetrate the stationary phase (that is, the gel particles) and are retarded differentially. When a solution of molecules of different size is passed through such a column, some of the smaller molecules are retarded so that the average molecular weight of the first fraction to be eluted is higher than that of the original mixture while that of the last fraction is lower. It follows, therefore, that the difference between the two values for the highest and lowest fractions is an indication of the pore sizes in the gel (that is, the greater the differences, the greater the number of molecules retarded and therefore the larger the pore sizes). If no fractionation occurs it may mean that the pore sizes are too small (that is, no molecules retarded) or, on the other hand, it could mean that the pores are so large that all the molecules are retarded equally.

In these experiments a sample of a very heterodisperse polystyrene[3] (molecular weights ranging up to 10^6) was loaded on to the top of a column of the material under test and was eluted with benzene. The polymer fractions were recovered by freeze drying and characterized by single point viscosity measurements, the results being expressed as reduced viscosity η_{sp}/C, a quantity related to the viscosity average molecular weight.

Initially swollen cross-linked polystyrene beads[4] and polyethylene gels were investigated since it was thought that in benzene these materials would have structures similar to the aqueous gels, cross-linked dextrans and starch. Good fractionation results were obtained (Table 1) but the most highly swollen gels tended to pack down and/or block the supporting glass sinters.

Table 1

Media used to pack the column	Fractions Highest $\eta sp/C$	 Lowest $\eta sp/C$
References		
Whole polymer	1.08	1.08

Silica gel 'Santocel *A*'	3.78	0.13
Other materials		
Crushed sintered glass porosity, 40μ	1.02	1.05
Corning porous glass No. 7930 porosity 40 Å	0.99	1.08
Porous pot	1.21	0.92
Fire Brick Johns Manville *C*22	1.82	0.80
Molecular sieve type 5*A*	1.59	0.90
Porous cement	1.63	0.84
Activated charcoal	1.33	0.99

Cellulose gels (Table 1) formed by the regeneration of gelled viscose solutions are firmer but the most porous ones have the disadvantage of tending to contract in the presence of benzene. It was decided, therefore, to look at even more rigid structures.

Porous glass would be ideal for gel filtration since presumably it could be used in a wide variety of conditions. Unfortunately, no fractionation was observed (Table 1) with (1) the Corning porous glass No. 7930 (porosity 40 Å) or (2) crushed sintered glass (porosity 40μ). However, since in one case the pores may be too small and in the other case too large, it seems likely that a glass with the appropriate porosity can be prepared. Meanwhile other porous materials have been examined.

Best results have been obtained with highly expanded silica gels which have a stability approaching that of glass showing little tendency to contract in a large number of solvents over a wide temperature range. With the gel 'Santocel *A*' the efficiency of fractionation was of the same order as that found with a conventional precipitation method[3] (Fig. 1), and it is suggested that columns of this material could be used for routine polymer fractionations. However, the use of these materials is not restricted to polymers, for silica gels can be prepared with a very wide range of porosities suitable for almost any molecular weight range.

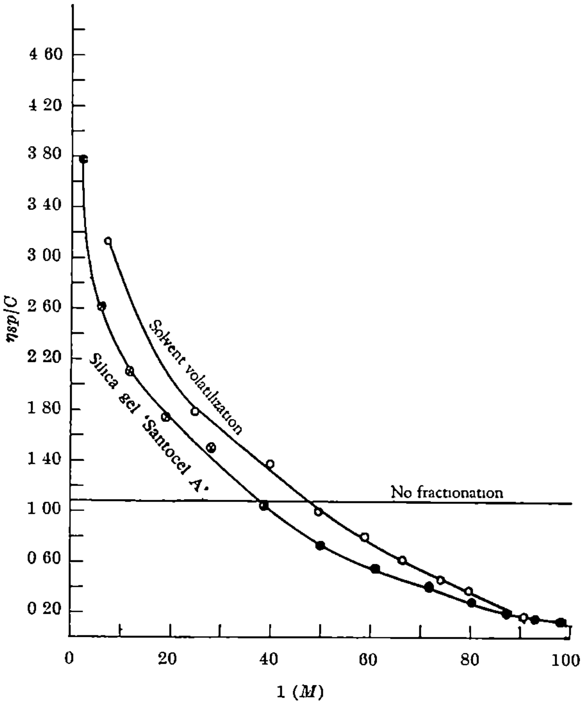

Fig. 1. Fractionation with silica aerogel 'Santocel *A*'. I (*M*), Cumulative weight fraction calculated for each fraction as total weight of all preceding fractions plus half the weight of the fraction, and then divided by total weight of all the fractions

Most of the other materials tested were very stable but the degree of fractionation obtained was poor. However, in some cases (for example, the Linde type molecular sieves, Johns Manville firebrick, etc.) the differences between the highest and lowest values of $\eta sp/C$ were large enough to indicate that these materials might be useful for the separation of lower molecular weight materials.

I thank Miss S. A. Monksfield and Mrs. H. M. Aplin, who carried out the fractionation experiments, Mr. R. G. Goldsmith, who prepared the gels and some of the other materials, and Monsanto Chemicals, Ltd., for the gift of the 'Santocel *A*'. This work is pub-

lished by permission of the Director of the National Chemical Laboratory.

RADIATION CHEMISTRY

Action of Ionizing Radiation on Rat Liver Cell Nuclei

The site of attack by OH radicals on the various components of some cell nuclei has been explored using the radiation-induced carboxylation technique recently described[1]. This involves irradiation of oxygen-free suspensions of the nuclei in the presence of sodium bicarbonate, under conditions where the radicals can react with the nuclear constituents. The negative polarons[2], $(H_2O)^-$, produced from the water react with the bicarbonate according to

$$(H_2O)^- + HCO_3^- \rightarrow CO_2^- + OH^- + H_2O \qquad (1)$$

In general, carboxylation depends on the formation of a free radical from an organic molecule (RH), for example, by the process

$$RH + OH \rightarrow R + H_2O \qquad (2)$$

and association of the free radical with the CO_2^- radical ion according to

$$R + CO_2^- \rightarrow RCO_2^- \qquad (3a)$$

$$RCO_2^- + H^+ \rightleftarrows RCO_2H \qquad (3b)$$

In order to assay the carboxylic acids produced in the various components of the nuclei, bicarbonate labelled with carbon-14 was used.

Nuclei were prepared from rat-liver by Dounce's method[3], involving homogenization with dilute citric acid at pH 4.0. The isolated nuclei were then suspended in phosphate buffer (4×10^{-3} M, pH 8.0) containing labelled sodium bicarbonate (6×10^{-3} M, 5 μc./ml.). The suspensions of the nuclei (0.2 mg/ml.) were evacuated and then irradiated with cobalt-60 γ-rays. After irradiation the nuclei were precipitated with perchloric acid (final concentration 0.4 M). Aliquots were assayed for activity after taking to dryness on planchets. The remaining nuclei were treated as follows. Lipids were extracted with ethanol and ethanol/ether (3:1) at 55° C. Nucleic acids (DNA and RNA) were then extracted by heating twice with 10 per cent sodium chloride at pH 8.0, and precipitated with ethanol. RNA was removed by treatment with 0.2 N sodium hydroxide at 80° C and the DNA reprecipitated. Removal of small amounts of contaminating protein from the DNA was achieved by incubation with pronase. Aliquots of each component were counted.

Table 1 records some of the results obtained. The actual experimental figures are given in terms of counts/min per mg of each component. The percentage of total activity in each fraction is also shown in Table 1. It can be seen that, of the total extent of carboxylation, only 3–4 per cent go into the DNA fraction, by far the major reaction occurs in the protein and lipids.

Table 1. Irradiation (cobalt-60 γ-rays) of suspensions of rat liver nuclei (0.2 mg/ml.) in phosphate buffer (4×10^{-3} M, pH 8.0) and in the presence of ^{14}C-labelled sodium bicarbonate (6×10^{-3} M, 5 μc./ml.), dose-rate 1.15×10^4 rads/min. (The figures in the parentheses give the percentage of total incorporation in each fraction)

Dose (rads $\times 10^{-4}$)	Total* (c.p.m./mg)	Lipids (c.p.m./mg)	Protein (c.p.m./mg)	RNA (c.p.m./mg)	DNA (c.p.m./mg)
3.45	342 (100%)	3,544 (31.2%)	216 (53.6%)	183 (1.1%)	110 (3.2%)
11.5	1,095 (100%)	9,688 (26.7%)	748 (57.8%)	398 (0.8%)	401 (3.6%)

* Recovery was about 90 per cent of the total activity.

The composition (per cent) of these nuclei was approximately. protein 85, DNA 10, RNA 2, lipid 3. Thus, even though the lipid fraction makes up only about 3 per cent of the bulk of the nuclei, it accounts for 30 per cent of the total incorporation, this is demonstrated by the high values of the counts/min per mg for this particular fraction. Such a high reactivity of the lipid material may be associated with its chemical nature as well as with the fact that it is predominantly in the nuclear membrane, and may thus 'trap' OH radicals generated in the ambient medium.

If one assumes that the different proteins present in the cell nuclei have undergone about the same degree of carboxylation, it would follow that in the protein, which is possibly more specifically associated with the DNA about 7 per cent of the incorporation has occurred, that is, the relative extent of carboxylation of the DNA and of the protein in the complex is in the ratio 1:2.

It should be pointed out that there may be certain qualifications on any absolute interpretation of the results obtained by the carboxylation technique. In particular, carboxylic acids produced at certain sites may be unstable and, furthermore, steric hindrance and other chemical factors may affect the reaction of the CO_2^- radical ion. The extent of such interference is, at present, unknown. Nevertheless, this appears to be a useful technique for a preliminary survey of certain features of the effects of ionizing radiations on more complex systems.

BIOCHEMISTRY

Appearance of New *N*-Terminal Groups by the Action of Rennin on Casein

Wissmann and Nitschmann[1], studying the action of rennin on α-casein by the method of Sanger[2], found, after the action of rennin for 30 min., not only the original *N*-terminal amino-acids arginine and lysine but also a new *N*-terminal amino-acid,

Table 1 NUMBER OF *N*-TERMINAL GROUPS (MOLE/10^5 GM DNP-PROTEIN) IN CASEIN AND PARACASEIN, DETECTED BY THE FLUORO-DINITROBENZENE METHOD

Correction factors for losses of DNP-amino-acids during hydrolysis were determined for DNP-casein All values were corrected with these factors

The increase of end groups as a whole after 10 min of rennin action is significant at the 5 per cent level, even if arginine is not considered

* Values which in the *t*-test differ significantly at the 5 per cent level from the corresponding values at zero minutes

namely, phenylalanine Thus these workers concluded that the non-protein nitrogen which is formed by the transformation α-casein → para-α-casein + non-protein nitrogen, results from the rupture of a peptide bond

By comparing the amounts of non-protein nitrogen which are set free after the action of rennin on different casein components, Wake[3] showed that the non-protein nitrogen originates from the κ-fraction This author also used Sanger's method to determine whether or not the release of non-protein nitrogen resulted from rupture of a specific peptide bond Observations made before and after rennin treatment of the κ-casein gave no indication of any difference in *N*-terminal groups Thus it was worth while re-investigating the problem of whether or not the splitting reaction is actually a specific proteolysis

We describe here the proteolytic activity of rennin, if any, during the formation of paracasein, and also our investigation of the effect of rennin on paracasein during a prolonged period of incubation The latter was done in order to obtain a decisive answer to the suggestion of Wake that the results of Wissmann and Nitschmann were due to proteolysis by rennin as the *p*H was lowered nearer to its point of optimum during the process of isolating the para-α-casein

The sodium-caseinate used in this investigation was prepared by the method of McMeekin *et al* [4], which avoids inclusion of milk protease For the incubation with rennin a 10 per cent solution of whole casein was prepared by dissolving the dry protein in distilled water by addition of 0 1 *N* sodium hydroxide and adjusting the solution to *p*H 6 6 The rennin was purified by zone electrophoresis to be described by Payens[5] Before incubation the rennin was dissolved in acetate buffer of *p*H 5 6 In these experiments 100 mgm /ml of casein solution was incubated with 0 004 mgm /ml of purified rennin at 30° C The activity of the rennin was established at 2,910,000 units by comparison with a standard preparation The rennin units used in this investigation are defined as the number of grams of normal milk which can be clotted at 35° C within 40 min by 1 gm of rennin

After the incubation the rennin was inactivated by heating at 70° C for 15 min Thereafter, each solution was dialysed for 48 hr against distilled water at 4° C and freeze-dried During incubation care was taken to prevent growth of micro-organisms

In order to follow the hydrolysis of paracasein, end group analysis was carried out according to the method of Fraenkel-Conrat *et al* [6], except that the determination of dinitrophenyl (DNP)-arginine was estimated by Biserte's method[7] The release of non-protein nitrogen from casein immediately after addition of rennin was followed by the method of Alais *et al* [8] The maximum yield of non-protein nitrogen estimated by this method was reached after 10 min It is generally assumed that within the same time the formation of paracasein from casein is completed Thus if the splitting reaction is based on the rupture of a peptide bond the appearance of a new *N*-terminal group might be expected within this time It is emphasized that even in the case that only one peptide bond per protein molecule is split, the method for end group analysis is sensitive enough to detect this extent of hydrolysis

As shown in Table 1, a significant increase occurred only in *N*-terminal arginine during the first 30 min An explanation of these results can be given in two different ways First, it may be suggested that during the splitting reaction peptide bonds are broken and new *N*-terminal arginine groups are set free It is also possible that by the action of rennin the *N*-terminal arginine groups become more easily available The latter would be in accordance with a recent suggestion of Alais and Jollès[9] that the liberation of non-protein nitrogen results from the splitting of an ether group between *N*-acetylneuraminic acid and a galactose group of the casein If this is true, no new end groups would be expected when rennin acts on κ-casein, as found also by Wake Considering the data in the literature and our own work, we came to the following interpretation

κ-casein can be considered as the factor which is responsible for the micelle stabilization of the casein complex[10] Through the action of rennin κ-casein is transformed and can no longer act as a protective colloid which encloses the calcium-sensitive groups of the casein complex As a result of this action the end groups of the casein components become more susceptible to attack by fluoro-dinitrobenzene and an increasing amount of arginine, which is the original end group, can be detected

Following the action of rennin with prolonged incubation a specific proteolysis of the paracasein is observed Especially those peptide bonds are split where methionine and phenylalanine are enclosed (see

Table 1) However, this specific protease activity could be detected only after an incubation time which was much longer than the minimum time for rennet clotting

On the basis of these results it is apparent that if the amount of phenylalanine found by Wissmann and Nitschmann was liberated by an increase of the proteolytic activity of the rennin, an increasing amount of methionine should also have been found Since Wissmann and Nitschmann did not find such a liberation of methionine, Wake's suggestion seems to be invalid

We thank Prof R Jenness, of the University of Minnesota, for his help, Dr T A J Payens for supplying purified rennin samples, and Mr H P Wijnand for technical assistance and statistical analysis of the results

Determination of Polygalacturonase in Fruits

The action of polygalacturonase[1] is most commonly investigated either by viscometry[2] or by the Willstatter-Schudel hypoiodite procedure[3] Recently, Foda[4] showed that the enzyme action was more conveniently and rapidly measured by using a colorimetric method based on that of Willaman and Davison[5]

A highly efficient extraction of polygalacturonase from a number of fruits has been made by the following method 30 gm of the macerated tissue were thoroughly stirred with 2 25 gm of a 10 1 (w/w) mixture of sodium chloride and the disodium salt of ethylenediamine tetraacetic acid, and then kept at 3° C for 15 min For macerates with a low dry matter content, the mixture was then centrifuged and the supernatant liquid filtered off To samples with a higher content of total solids, 20 ml of a 7 5 per cent solution of the salt mixture was stirred in first, left for a further 15 min and then centrifuged and filtered In all cases the remaining slurry was extracted with additional 20 ml portions of the salt solution until at least 60 ml had been collected All extracts were kept below 3° C The procedures used by Foda[4] for precipitating, washing and dissolving the enzyme were not altered

In the determination of polygalacturonase in plant extracts it is usual for the aliquots taken from the reaction mixture at various time intervals to be made either strongly acid[4] or alkaline[6], in order to stop further enzyme activity But exposure of the partially purified enzyme to *p*H 0 6 and to *p*H 10 0 has been shown to reduce but not eliminate the activity[7] The surface active agent 'Teepol', added to the sample to a concentration of 1 0 per cent (v/v), is, however, completely effective in preventing continued enzyme action

The substrates of Jansen acid[6], Ehrlich acid *C*[8], Wichmann pectic acid[8], McCready acid[9] and partially neutralized McCready acid[10], in comparable concentrations, were reacted with standard amounts of polygalacturonase from tomato fruit The five acids showed a decreasing rate of reaction in the above order, with the first three substrates mentioned being almost equally acceptable to the enzyme Hence the utilization of Wichmann pectic acid, the most usual substrate for polygalacturonase, was continued

In the method of Foda[4] the reducing groups in 1 ml of the samples of the reaction mixtures were estimated by heating them for 1 hr at 100° C with 2 ml of saturated picric acid and 1 ml of 20 per cent (w/v) sodium carbonate in a stoppered graduated test-tube After cooling, the reactants were diluted to 10 ml with water But the excess substrate formed a precipitate at this stage and the turbidity thus produced affected the subsequent absorption readings By diluting with absolute ethanol instead of water, however, it was found that the pectic acid could be coagulated The tubes were then shaken, left for 1 hr at 3° C with occasional stirring, centrifuged, decanted and centrifuged again, resulting in an optically clear solution A series of standard solutions containing 0–0 80 mgm of α-D-galacturonic acid monohydrate per ml and 1 0 per cent (v/v) 'Teepol' gave a linear increase in optical density There was also a straight line relation between the enzymatic production of reducing end groups and the time of reaction, provided that the increase in reducing power from a 0 25 per cent (w/v) solution of Wichmann pectic acid was kept within the above limits

Table 1 Activity of Polygalacturonase in Various Fruits

Common name	Scientific name	Percentage of dry matter in the macerated fruit §	Activity
Tomato (variety 'Potentate')*	*Lycopersicon esculenteum*	6 1	3 68
Avocado†	*Persea gratissima*	22 3	0 24
Medlar†	*Mespilus germanica*	24 4	0 10
Pear (variety 'Doyenne du Comice')*	*Pyrus communis*	15 8	0 06
Pineapple†	*Ananas comosus*	19 6	0 09
Cranberry*	*Vaccinium macrocarpum*	12 9	0
Persimmon*	*Diospyros virginiana*	20 7	0
Cucumber (variety 'Butcher's Disease Resister')*	*Cucumis sativus*	4 4	0
Tangerine†	*Citrus nobilis*	12 1	0
Carrot*	*Dorcus carota*	9 8	0
Melon†	*Cucumis melo*	15 5	0
Grapes‡	*Vitis vinifera*	21 3	0

* Whole fruit
† Flesh only
‡ Whole fruit with seeds removed
§ Dried for 48 hr at 80° C in a forced draught oven

The activity is given as increased reducing power, expressed as gm galacturonic acid monohydrate per 100 gm fresh weight of ripe fruit per hour

A measure of the activity of polygalacturonase to be found in a number of species, using these modifications, is given in Table 1 Although claims for the presence of the enzyme in both cucumbers[11] and carrots[12] have been made, these were not confirmed The activities previously shown were obtained only through the use of long reaction periods in conjunction with viscometry in the former and chromatography in the latter case No attempt has yet been made to find how the activity of the enzyme is affected by the inhibitors which are undoubtedly present in some fruits[13]

β-Glucuronidase in the Rat Placenta

Histochemical investigations, using the ferric hydroxyquinoline method of Fishman and Baker[1], indicate that the β-glucuronidase of the fully established rat placenta is predominantly fœtal As early as the 9-day stage there is moderate activity in the embryonic structures At 11 days an intense reaction is obtained in the endoderm of the visceral yolk sac, in the trophoblast and giant cells of the central zone and ectoplacental cone and in the endovascular plasmodium growing into the decidual arteries The activity of the visceral yolk sac remains high, with a terminal drop in the last two or three days of pregnancy The giant cells, the junctional zone trophoblast and the endovascular plasmodium, with the exception of the glycogen cells, retain a high activity until about the 19th day, but the labyrinthine activity begins to fall off at about 15 days By the 22-day stage the reaction in all the trophoblastic structures is greatly reduced

In the early stages of implantation there is considerable activity in the uterus, with a moderate reaction in the cells of the antimesometrial decidua except for the implantation zone[2] and the peripheral fibrinoid capsule[3] The reaction in the mesometrial decidua is principally confined to the endothelial linings of the blood vessels, particularly in the decidual cone[4], and to a few decidual cells The uterine muscle, the uterine epithelium and the blood vessel walls of the mesometrium react strongly throughout pregnancy, but by the 11-day stage the reaction in the decidua basalis is minimal and is restricted to the blood-vessel walls and to a few metrial gland cells The anti-mesometrial decidual cells continue to react as long as the capsularis persists, but the decidua basalis is unreactive during the whole period of its degeneration and disappearance

In view of our uncertainty of the functions of β-glucuronidase *in vivo* these findings are of some interest A possible explanation of the trophoblastic enzyme is that it is concerned with the conjugation of œstrogenic hormones reaching it from the maternal blood, thus limiting interference by maternal œstrogens in the genital development of the fœtus The total of the several placentæ of a litter must represent a significant enzyme activity and may play an important part in the conjugation of pregnancy œstrogens The reduction in the trophoblastic activity during the last few days may be related to a changing proportion of conjugated and free œstrogens in the maternal blood in the immediate *pre-partum* period, such as Cohen, Marrian and Watson[5] described in the human The enzyme in the visceral yolk sac could have a similar function to that suggested for the trophoblast, conjugating œstrogens diffusing through from the uterine lumen It does in any event seem more reasonable to suppose that the β-glucuronidase of the placenta is concerned with the formation rather than with the hydrolysis of glucuronides It may even be that the trophoblast is a 'target organ' for œstrogenic hormones and that the trophoblastic enzyme is concerned with the fixation, metabolism and physiological action of œstrogens, as Fishman[6] has suggested for sex tissues generally, instead of with their inactivation

The relatively low activity of the maternal placenta is probably due to the high level of circulating corpus luteum hormone, since there is evidence that in some situations the administration of progesterone prevents the rise in β-glucuronidase activity associated with œstrogens[6] On the other hand, the considerable reaction in the antimesometrial decidua is difficult to correlate with this It is interesting, in view of the inverse relationship reported by Harris and Cohen[7] between esterase activity and β-glucuronidase activity in the uterus, that with the exception of the visceral yolk sac, which is rich in both enzymes, there is an approximate inverse relationship between the placental distributions of naphthyl acetate-esterase and β-glucuronidase For example, esterase activity only appears in the trophoblast during the last few days of pregnancy, when the β-glucuronidase activity is falling off

Possible Production of Several Exopenicillinases by *Bacillus cereus*

During the course of an investigation of the specificity of protein synthesis in *Bacillus cereus*, the proteins excreted by this micro-organism in exponential growth have been isolated and examined with the help of a variety of techniques Among these proteins, the enzyme penicillinase is found

Bacillus cereus, penicillinase constitutive strain derived from N C T C 569 [1], was grown aerobically in Roux flasks using the medium described by Kogut *et al* [1] and including 0 02 M citrate[2] At the end of the culture, the *p*H was lowered to 6 0 with a few ml of 3 M citric acid, and, after centrifugation in the cold, the supernatant was lyophilized immediately The powder was afterwards redissolved in a minimum amount of distilled water, and the concentrated solution so obtained submitted to a column treatment on 'Sephadex *G*-50', allowing a 73 per cent recovery of the proteins in the form of a solution at *p*H 6 10

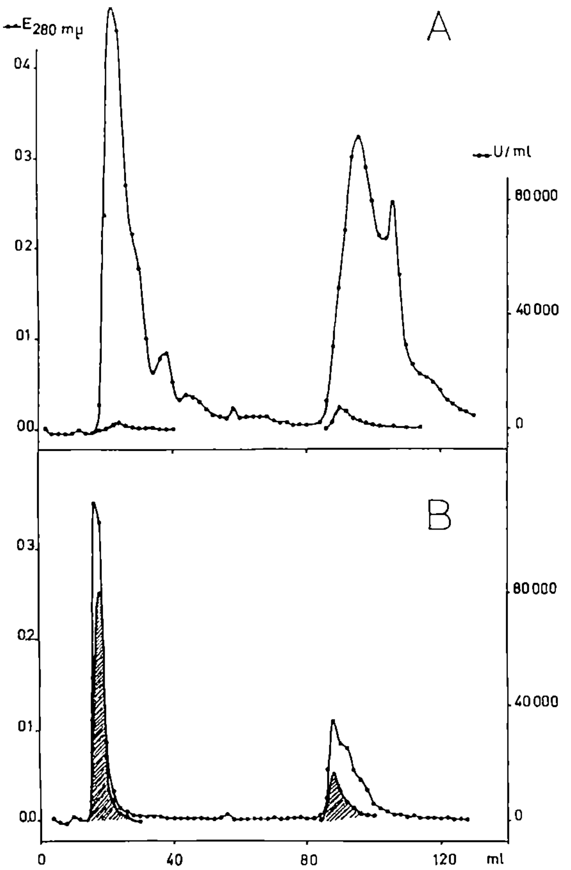

Fig 1 Chromatography on DEAE-cellulose, Cl⁻ form (1 × 32 cm), of proteins from the supernatant fluid of *Bacillus cereus* cultures (*A*) total exterior proteins, (*B*) purified penicillinase The gradient (linear change from 0 to 3 M sodium chloride over 200 ml) started at effluent volume 80 ml protein recoveries, based on the value of $E_{280\ m\mu}^{1\ cm}$ for the different fractions as compared with the corresponding value for the sample applied to the column, were quantitative in both cases Penicillinase activities, also quantitatively recovered, were determined by a microtitrimetric procedure[8], at *p*H 6 50, the units being the same as used by Perret[9] The scales are the same in both parts of the diagram, and those for ultra-violet extinction and activities were adjusted so as to conform to the data of Kogut *et al* [1] on the extinction coefficient of crystalline penicillinase at 280 mμ

in 0 005 M acetic acid–pyridine buffer, and free of other contaminants After lyophilization of the pooled protein fractions, the powder obtained was examined by column chromatography on DEAE-cellulose previously equilibrated with 0 005 M piperazine-hydrochloride buffer[3] *p*H 6 10, and using a linear sodium chloride gradient The result obtained is depicted in Fig 1*A*

It is apparent from this diagram that, under these conditions, penicillinase activity is distributed in two well-separated peaks The existence of two protein fractions exhibiting penicillinase activity can also be demonstrated qualitatively in the same material as here on agar-gel electrophoresis plates, excluding the possibility of a chromatographic artefact, and this observation is substantiated on the total exterior proteins from the constitutive strain of *Bacillus cereus* as well as on similar extracts prepared from the inducible strain grown in presence of penicillin It is, furthermore, noteworthy that purified penicillinase prepared according to Kogut *et al* [1] up to (and including) the precipitation in saturated ammonium sulphate also exhibits the same two enzymatically active fractions as here when chromatographed under the same conditions as the total exterior proteins (Fig 1*B*) , the active components, however, appear in reverse proportions It might be mentioned finally that both protein fractions are similar on the basis of their resistance to iodine[4,5], and correspond well to α-penicillinase

The possibility therefore seems to exist that penicillinase is excreted by *Bacillus cereus* in the form of two distinct protein species, at least , one of these, being positively charged at *p*H 6 10, must have an isoelectric point fairly different from that of the crystalline preparation of Kogut *et al* [1] It is not clear at present whether the two penicillinases are produced simultaneously, or if a phenomenon of limited proteolysis[6] is involved It is known, indeed, that the supernatants of *Bacillus cereus* contain a protease[2], which might resemble the subtilisin of *Bacillus subtilis* When, on the other hand, the proteins excreted by *Bacillus cereus* are isolated by successive dialyses and lyophilizations at neutral *p*H, a large number of protein species can be separated by agar-gel electrophoresis which react specifically with penicillinase-antibody, the production of which has been induced in rabbit serum by injections of the same purified penicillinase already mentioned, and several of these components seem to be still enzymatically active This suggests that penicillinase is susceptible to discrete proteolytic degradation without loosing its activity The conditions used in the present work (0 02 M citrate, *p*H 6 10), however, do not favour a proteolytic action of the subtilisin type[2,7], at least after the growth period

Further work is in progress in order to clarify this point, to characterize the two penicillinase components immunologically and to refine the chromatographic purification of penicillinase as suggested by the results of Fig 1

We thank Prof H Chantrenne for his advice The financial assistance of the Rockefeller Foundation is gratefully acknowledged

Synthesis of 'Bacterial' Protein by Cultured Chick Cells

Primary isolates of chick embryo fibroblasts cultivated as monolayers were found to resume protein synthesis only after a delay of 24–48 hr The extent of the lag period was dependent in part on the composition of the medium with which the cells were nourished following release from the embryo by trypsinization A marked shortening of the lag was

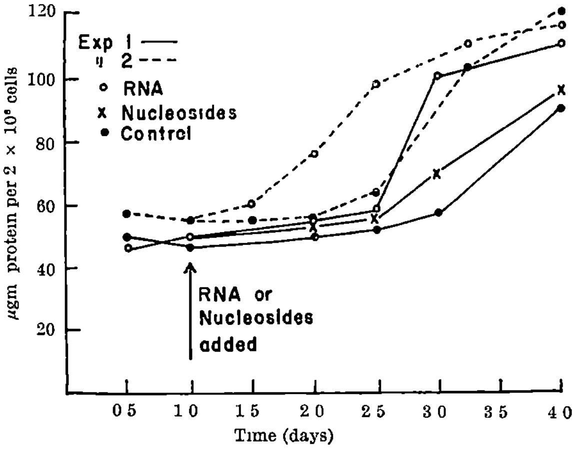

Fig 1 Protein synthesis in RNA-treated cells In both experiments 300 μgm RNA from the soluble fraction of *E coli B* was added at day 1 and remained in contact with the cells throughout Exp 1, medium contained 1 5 per cent horse serum, nucleosides 100 μgm each of four major RNA components, Exp 2, medium contained 3 per cent horse serum

observed when phenol-extracted ribonucleic acid (RNA)[1,3] was added to the medium shortly after the cells became attached to the glass (Fig 1) The effect was abolished by pretreatment of the RNA with ribonuclease and was not duplicated by combinations of nucleosides RNA preparations obtained from chick embryo, rabbit liver, or *Escherichia coli B* proved equally effective

The distribution of 'active' RNA in bacteria resembled that of the so-called 'messenger' fraction of other investigators[4,5] This similarity suggested that cells responding to heterologous RNA might be synthesizing protein characteristic of the donor cell

The protein of choice would be an enzyme produced by the donor of RNA, but not ordinarily by the recipient cell However chick cells exposed to *E coli* RNA could not be shown to synthesize β-galactosidase or ornithine transcarbamylase

A second choice was protein with the antigenic characteristics of bacterial proteins, which might be detected with antiserum directed against *E coli* protein Each RNA messenger molecule is a potential contributor of antigenic information as opposed to a small minority bearing information for the synthesis of a particular enzyme Moreover, full functional integrity of the messenger is perhaps not necessary for the replication of antigenic determinants

When protein released from chick cells by grinding or sonic treatment followed by ammonium sulphate precipitation was reacted in a complement fixation test with such an antiserum duly absorbed with chick embryo tissue, reactive material was detectable only in cells exposed to *E coli* RNA, and increased in quantity with time (Table 1) Untreated cells had no detectable amount of bacterial' protein

Table 1 COMPLEMENT FIXATION WITH PROTEIN FROM CHICK CELLS VERSUS ANTI-*coli B* ANTIBODY

		Exp. 1	Exp 2	Exp 3	Exp 4

	day 3	—	32	—	—

* Units of complement-fixing antigen per 0 5 mgm of cellular protein Values expressed as the reciprocal of the highest dilution of the protein sample showing at least 2+ complement fixation The system contained eight units of anti-*coli B* protein antiserum (absorbed with chick cell homogenate)

It remained, however, to demonstrate conclusively that the reactive protein was synthesized subsequent to the addition of RNA and did not arise from the modification of preformed protein resident in the cells or from the release of protein introduced with the RNA Convincing evidence of *de novo* synthesis might be obtained by labelling with L-leucine-^{14}C protein synthesized following contact with RNA 'Bacterial' protein isolated from other cellular proteins by precipitation with specific antiserum should be labelled if synthesized *de novo* For this purpose, uniformly labelled L-leucine-^{14}C was added to the culture medium immediately after the RNA At intervals cells were collected and the protein was liberated by sonic treatment or grinding Following separation from the cell debris by centrifugation, the protein was precipitated with ammonium sulphate and redissolved after dialysis, in veronal buffer at *p*H 7

The specific radioactivity of all the newly synthesized protein was determined, and specific precipitates were formed by reacting the cell protein with rabbit antiserum to *E coli B* protein, followed by goat or horse anti-rabbit γ-globulin The proportions of the rabbit γ-globulin–anti-rabbit γ-globulin reactants were selected for precipitin equivalence When only rabbit serum specific for *E coli* protein was added, no precipitate was formed

Whatever the source of the cellular protein, the precipitating system (rabbit serum + anti-rabbit γ-globulin) gave precipitates of similar total protein However, significant radioactivity was associated with the washed precipitate only when protein synthesis occurred in cells exposed to *E coli* RNA (Table 2)

Table 2 BACTERIAL PROTEIN SYNTHESIS DETERMINED BY SPECIFIC IMMUNOLOGIC PRECIPITATION

* *E coli* RNA from soluble fraction, 300 μgm /10 ml of culture remained in contact with cells throughout the experiment

RNA from chick embryos stimulated protein synthesis just as did its bacterial counterpart, but elicited no synthesis of material precipitable by the antisera utilized When the antiserum to *E coli* protein was replaced by normal rabbit serum or serum from rabbits immunized against influenza virus, the precipitates contained no significant radioactivity In response to bacterial RNA, some 5–15 per cent of newly synthesized protein could be shown to possess the antigenic character of *E coli* protein A tentative interpretation of the time-course suggests a limited period of effectiveness of the RNA

These results indicate that some molecular species of RNA obtained from *E coli B* penetrate into chick embryo fibroblasts and influence the synthesis of protein This RNA not only accelerates protein synthesis but also provides specific information for the antigenic character of the protein The latter function in intact cells resembles that observed for messenger RNA in sub-cellular protein-synthesizing systems[4,5] It also resembles the role of the RNA of plant and animal viruses in the infected cell

This function of bacterial RNA in a chick cell lends support, however modest, to the concept of a universal RNA code in biological systems The fact that the protein formed was not precipitable by specific antiserum alone and proved but weakly reactive in the fixation of complement suggests that it is not identical to *E coli* protein The evidence could be interpreted to point toward small univalent molecules (haptens) or hybrids with a minor bacterial component as the products

Effects of Standing on the Protein Extracts of Barley Grain

DURING investigations on the water-soluble proteins of barley grain we have found that a few days standing has pronounced favourable effects on the extracts While standing a small precipitate is formed This precipitate contains only about 3 per cent of the total protein in the extract Paper-electrophoreses of fresh extracts after 1–2 h extraction time are very blurred After 2–7 days standing electrophoresis shows a good separation of eight fractions[1] The fresh extracts also yield irreversible precipitates on ammonium sulphate fractionation, dialysis against water or freeze drying After some days standing no irreversible precipitation occurs

A survey of other work on the water-soluble proteins of plant seeds indicates a similar tendency In work on barley[2–5], wheat[6], *Ricinus*[7] and *Jatropha*[8] proteins, one of the two equivalents of standing—very long extraction time (12–48 h) or prolonged dialysis against buffer—have been used

It is generally believed that most of the irreversible precipitates which form on fractionation of seed proteins are protein–phytate complexes[9] We have, however, also found large amounts of carbohydrates in some precipitates (quantitative anthrone test) Furthermore, the strange blurring patterns of the paper-electrophoreses are probably caused by the high viscosity of fresh extracts due to polysaccharides Accordingly, we tested whether the water-soluble polysaccharides and phytate are hydrolysed while the extract was standing

100 g of finely ground acetone-treated barley was extracted for 1 h at 4° C with 200 ml water with occasional stirring The slurry was centrifuged at 16,000 r p m for 10 min at 4° C The clear extract was incubated at 4° C and the hydrolyses of phytate and polysaccharide were followed by measuring the inorganic phosphate and viscosity of the extract The results are shown in Fig 1 It is clear that the two reactions occur and are completed within 5 and 2 days respectively The increase in phosphate must be due to hydrolysis of phytate as there are not sufficient amounts of other hydrolysable phosphoric acid esters in barley grain When phytate was added to the extract it was also hydrolysed at a rate corresponding to the increase of inorganic phosphate during the incubation of the extract

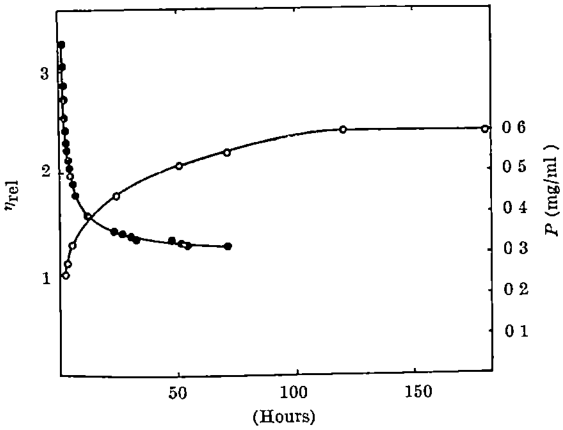

Fig 1 Increase of inorganic phosphate (○) and decrease of viscosity (●) of water extract of barley grains while standing at 4° C

The high viscosity of the extracts caused by polysaccharides and the formation of protein–phytate complexes interfere in protein fractionation of fresh extracts After some days standing of the extracts, fractionation is possible This is, we believe, due to the two reactions demonstrated in this work

PHYSIOLOGY

Inverse Caloric Nystagmus obtained by Unilateral Stimulation of the Cat

FOR descriptive purposes, two types of inverse nystagmus may be differentiated (1) secondary nystagmus, wherein responses opposed in direction to a primary reaction occur shortly after the primary has declined , (2) homolateral nystagmus, wherein the first (the primary) response to the stimulus has a direction opposite to the normal primary reaction The occurrence of a secondary reaction to rotatory

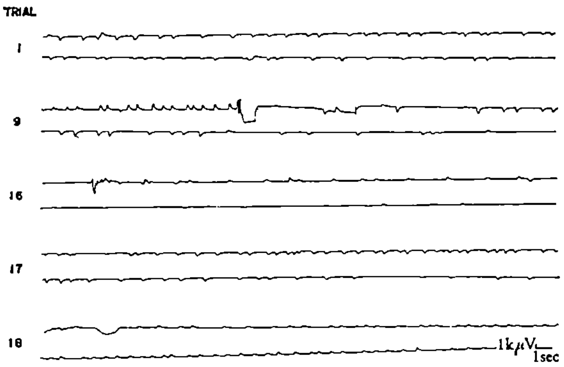

Fig 1 Nystagmus recordings from a cat stimulated in total darkness with a series of unilateral calorizations The nystagmus tracings cover a 66-sec period immediately after stimulus cessation Upward deflexions of the recording pen indicate eye movements to the right, downward deflexions indicate eye movement to the left Examples of secondary nystagmus (trial 9) and of homolateral nystagmus (trials 9, 16, and 18) are clearly evident Stimulus water 3–5° C applied to right ear for 15 sec

stimuli has been frequently observed in both man and animals[1–5] However, with unilateral caloric stimulation of man under usual testing conditions, the secondary apparently does not occur[1]

Although very little information is available with respect to inverse nystagmus and aural irrigation of animals, Riskaer and Permin have noted some occurrences of both secondary and homolateral nystagmus obtained by unilateral calorization of rabbits[6] Kristensen, however, reported uniform and appropriate nystagmus from rabbits unless the head was lowered 15°–20° from normal[7] Under the latter condition, inverse nystagmus appeared

The results reported here were obtained from one of several cats which demonstrated both secondary and homolateral nystagmus to unilateral caloric irrigation during previous testing sessions The animal was restrained, and its head held in the position of normal carriage, according to the casting method of Crampton, Schwam and Warburton[8] Needle electrodes were inserted into the skin at the outer canthi and a ground electrode was located near the mid-line of the skull Recordings of the horizontal components of eye movement were made on an Offner type *T* electroencephalograph using a 1 4 sec RC time constant in amplification

The stimulating apparatus consisted of a 2-qt water-bath with attached tubing and a glass nozzle, an adjustable stand to provide a 2-ft head of water, and a pan to collect the return flow from the ear Water temperature immediately prior to each trial was maintained at 3 0°–5 0° C

The animal was stimulated for 15-sec periods Nystagmus was recorded in total darkness during, and for several minutes following, irrigation Trials were spaced by rest periods of 10–12 min in full-room illumination

Records obtained from this animal appear in Fig 1 During the first 6 trials, a brisk response in the appropriate direction was obtained on termination of stimulation This was followed by a secondary reaction in the next 2 trials A clear homolateral response occurred during trials 9, 10, 11, 16, and 18 Intervening and following trials yielded an appropriate response

These results indicate that inverse nystagmus may occur in cats as a result of unilateral caloric stimulation It apparently does not occur in all such animals However, the sequence of events seems more orderly than that reported for rabbits by Riskaer and Permin[6] In the cats exhibiting the reaction an appropriate response was obtained in early trials, and was followed by a reverse reaction—the secondary Homolateral nystagmus appeared only after a number of calorizations, and was not observed without a secondary having appeared in earlier trials Further information on the occurrence of this reaction under different stimulus conditions is in preparation[9]

The results were collected at the U S Army Medical Research Laboratory, Fort Knox, Kentucky

An Alveolar-Arterial P_{CO_2} Discrepancy

REPORTS in the literature have indicated that the infusion of *tris* (hydroxy-methyl) amino methane (*tris*) results in increased blood *p*H and carbon dioxide content, with no change or a lowering of P_{CO_2} (ref 1) Pulmonary ventilation has been reported to decrease, while large amounts of 'bicarbonate' are excreted through the kidneys[2] These results have been interpreted in part as showing a respiratory centre responsiveness to *p*H in the absence of a change in P_{CO_2} (ref 2)

In an attempt to measure the effect of *tris* and another amine, arginine (free base), on acid-base balance and excretion of carbon dioxide by the lungs and kidneys, it soon became apparent that, with fixed ventilation a discrepancy existed between arterial P_{CO_2} as calculated from the Henderson–Hasselbalch equation and alveolar P_{CO_2}, found from measurements of expired gas, following the administration of these amines The experiments to be reported do not provide an explanation for this discrepancy However, caution is suggested in using these calculated values until this discrepancy is satisfactorily explained

Mongrel dogs were anæsthetized with 'Nembutal' (intravenous), tracheal intubation performed, and ventilation controlled throughout the entire experiment at a constant rate and volume by means of a mechanical respirator After 30–60 min of controlled ventilation, arterial blood and expired gas were collected Blood *p*H was immediately measured anaerobically at 38° C with glass electrode *p*H meter, plasma carbon dioxide content measured by the manometric method of Van Slyke, and blood P_{CO_2} (Pa_{CO_2}) calculated from the Henderson–Hasselbalch equation, using a pK' of 6 10 The volume of expired gas was measured in a Tissot gasometer, and its oxygen and carbon dioxide content measured by the method of Scholander Alveolar ventilation was calculated from the equation alveolar ventilation in l /min *BTPS* = 0 8658 times carbon dioxide expired in c c /min *STPD* divided by Pa_{CO_2} in mm mercury[3] Following two such measurement periods *tris* or arginine was given intravenously at the rate of 0 33 m mole/kgm /min 45–60 min after the beginning of one of the experiments, arterial blood and expired gas were collected and analysed as before At this time the alveolar ventilation formula was used in the form $Pa_{CO_2} = 0\ 8658\ X\ V_{ECO_2}/V_A$, on the assumption that the V_A computed during the control periods still obtained (It is probable that experimental V_A was less than control since, despite constant V_I, experimental V_E averaged 92 6 per cent of control V_E due to reduced V_{CO_2} To assure calculation of the maximum possible Pa_{CO_2}, the entire measured decrease in V_E was subtracted from control V_A for this calculation Thus the actual P_{CO_2} discrepancy may be greater than reported here) The value of Pa_{CO_2} so obtained was compared with that calculated from the Henderson–Hasselbalch equation

For comparison, experiments are included which were carried out in the same way, but in which acid-base balance was varied by either hyperventilation or hypoventilation throughout the experiment, or by the administration of sodium bicarbonate or various organic acids following the control periods

The high degree of accuracy with which arterial P_{CO_2} may be computed by the technique used here is indicated by the results of the control series In 39 such experiments the Henderson–Hasselbalch P_{CO_2} differed from that derived from the expired gas by a mean of − 0 2 mm mercury ± 1 5 (*S D*) This close agreement was found despite the unsteady state present during hyperventilation and acid or bicarbonate infusion, in experiments where *p*H ranged from 6 68 to 7 81, carbon dioxide from 3 2 to 61 1, and P_{CO_2} from 3 3 to 69 However, it is apparent from Table 1 that during the infusion of *tris* or arginine, blood P_{CO_2} calculated from the Henderson–Hasselbalch equation is substantially higher than that derived from expired air in every instance (range + 6 to + 104 mm mercury, mean + 22 4)

The explanation for this highly significant discrepancy is not given by these experiments If, at equilibrium, there were significant amounts of a compound other than the bicarbonate salt of *tris* or arginine present (such as the carbamate), the *pK'* of the system might be expected to differ from that of the usual $(BHCO_3^-)$—(H_2CO_3) system However, tonometry experiments have shown that, at equilibrium, the commonly used *pK'* of about 6 10 for the Henderson–Hasselbalch equation properly describes the relationships among *p*H, P_{CO_2}, and 'total carbon dioxide'

These findings are also similar to those we and others have found following the administration of carbonic anhydrase inhibitors[4] Experiments on dogs with 'Diamox(*R*)', performed exactly as described here, have also shown a higher P_{CO_2} on the basis of the Henderson–Hasselbalch equation A similar effect has been noted with carbonic anhydrase inhibitors in man with ventilation fixed by maximal exercise[5] The probable cause of these findings has been well discussed by Berliner and Orloff[4], who point out that equilibrium between carbon dioxide and bicarbonate is not so rapidly attained in the pulmonary capillary in the absence of carbonic anhydrase and that this could lead to a difference between alveolar carbon dioxide tension and that found in arterial blood *Tris* is known to affect certain enzyme systems[6] The possibility exists that *tris* and other basic amines might also have an effect on carbonic anhydrase Though the possibility may be entertained that a true diffusion gradient for carbon dioxide occurs, this seems most unlikely in view of the high solubility of this gas Thus it may be that these findings result from a state of disequilibrium, due either to formation of an intermediate compound or to interference with the enzymatic release of carbon dioxide in the lungs

Table 1 PLASMA CHEMISTRIES DURING CONTROL AND EXPERIMENTAL PERIODS

		Control			During infusion			
		*p*H	(CO_2)s m mole/l	P_{CO_2} (*H–H*) mm Hg	*p*H	(CO_2)s m mole/l	P_{CO_2} (*H–H*) mm Hg	P_{CO_2} (V_A) mm Hg
Tris	1	7 23	23 6	54	7 83	43 1	26	16
	2	7 39	21 8	35	7 64	33 1	31	23
	3*a*	7 36	24 8	43	7 66	40 2	36	21
	3*b*				7 73	45 4	34	26
Arginine	1	7 26	22 9	49	7 67	42 9	37	18
	2	7 07	27 6	89	7 23	66 9	153	49
	3	7 33	22 8	42	7 55	33 3	38	29
	4	7 32	23 1	44	7 35	26 6	47	41

(*H–H*) indicates P_{CO_2} derived from the Henderson–Hasselbalch and (V_A) that from the expired gas calculations

Whatever the reason, it seems clear that calculation of any of the parameters of the Henderson–Hasselbalch equation from measured values of the others during infusion of *tris* or arginine-free base may be subject to considerable error Hence any attempt to correlate such calculated values with changes in respiration must be made with due caution

Effect of Œstradiol on Phosphorylase Activity of Intrasplenic Ovarian Graft in C57*BL* Mice

NON-TUMORAL intrasplenic ovarian tissue of mice utilizes appreciable amounts of endogenous glycogen[1] Œstradiol, an inhibitor of the ovarian intrasplenic development[2], increases the glycogen content of ovarian graft when parenterally given to mice, while the weight of the graft is greatly reduced[3] This would suggest that hormonal repression at the hypophysis-level somehow interfered with metabolic reactions involved in the synthesis and/or degradation of glycogen Glycogen utilization is mediated through phosphorylase while it is synthesized by glucose transfer from uridine diphosphoglucose[4] It is a well-established fact that phosphorylase activity is

Table 1 PHOSPHORYLASE ACTIVITY IN NORMAL AND INTRASPLENIC OVARIES
(All values in μmoles/100 mg fresh tissue/10 min)

Conditions	No of ovaries	Average weight of the ovaries (mg)	No of experiments	With 5′AMP	Without 5′AMP	Ratio of activity $\frac{\text{without 5′AMP}}{\text{with 5′AMP}}$
Normal ovaries	101	3 3 ± 0 10*	5	7 0 ± 0 77	5 5 ± 0 46	78
Intrasplenic ovaries	22	17 7 ± 1 2	5	5 9 ± 1 7	6 4 ± 1 7	110
Intrasplenic ovaries plus œstradiol	33	9 1 ± 0 6	6	4 7 ± 0 44	1 9 ± 0 79	41

* *S E*

under hormonal control Thus muscle and liver phosphorylase *b* are activated to phosphorylase *a* by epinephrine[5] and glucagon[6] Furthermore, adrenocorticotrophic hormone specifically activates adrenal gland phosphorylase[7]

This communication indicates that œstradiol treatment decreases the ratio phosphorylase *a* to *b* in intrasplenic ovarian tissue possibly by depression of the follicle-stimulating hormone The method of Cori and Illingworth[5] for phosphorylase activity determination was adopted Castrated adult female mice of the *C57BL* strain from our colony, bearing one ovary into the spleen for 60 days, were utilized As previously[3], 10 μg daily of an aqueous suspension of 17β-œstradiol were injected intraperitoneally for 10 days Non-injected ovarian grafted females of the same age as well as non-injected normal females were used as controls The ovarian graft was recovered from the spleen by careful dissection of any splenic parenchyma macroscopically visible After weighing an adequate number of ovaries, they were pooled and homogenized in cold 0 15 M potassium fluoride An aliquot of the homogenate containing 6–12 mg (fresh weight) of tissue was used for the enzymatic assay The reaction mixture in a final volume of 0 6 ml contained 12 μmoles glucose-1-phosphate, 6 μmoles adenosine monophosphate (5′AMP), 0 6 μg glycogen, and 40 μmoles glycylglycine buffer, *p*H 6 0 The temperature was 30° and the incubation period 10 min When indicated, adenosine monophosphate was replaced by distilled water Each determination was carried out in duplicate The reaction was stopped by the addition of 1 8 ml of 10 per cent trichloroacetic acid Inorganic phosphorus in the acid supernatant was measured by the method of Fiske and Subbarow[8]

From Table 1 it is evident that œstradiol decreases the phosphorylase activity of intrasplenic ovary, that is, from 6 4 ± 1 7 μmoles of inorganic phosphorus/100 mg fresh tissue, to 1 9 ± 0 79 μmoles of inorganic phosphorus/100 mg fresh tissue, provided that 5′AMP is omitted When the latter is added, no significant effect of œstradiol is observed In normal as well as in non-injected intrasplenic ovaries, the ratio-activity without 5′AMP/activity with 5′AMP is above 65, which according to Cori *et al* [5] indicates that phosphorylase predominantly is in the *a* form On the other hand, the same ratio for intrasplenic ovaries under the influence of œstradiol is only 41, which indicates that phosphorylase is in the *b* form in this case

Purves and Griesbach[9] have shown that in spayed females rats the glycoprotein content of the gonadotroph cells of the hypophysis disappear under œstradiol treatment concomitantly with the gonadotropic potency Furthermore, Miller and Pfeiffer[10] observed that mice bearing intrasplenic ovarian tissue maintain a high level of blood follicle-stimulating hormone On the basis of these findings, one is tempted to correlate the suppression of the follicle-stimulating hormone by œstradiol treatment to the changes in activity of the intrasplenic ovary phosphorylase Thus, the follicle-stimulating hormone would be specifically involved in the activation of intrasplenic ovarian phosphorylase

Work to establish whether this mechanism applies to intrasplenic ovary or in addition to normal ovary is now being carried out

Fœtal Synthesis and Transplacental Passage of Homologous Serum Proteins in the Rabbit

BRAMBELL *et al* [1] have demonstrated the passage of various antibodies from the mother to the fœtal rabbit It may now be considered that such passage is not a special property of antibodies, since it has been shown[2,3] that heterologous serum proteins, when injected into the mother, appear intact in various compartments of 19–21 and 24–26 day rabbit fœtuses If transplacental passage of large molecules is indeed a general phenomenon of normal development, it is clearly of importance to ascertain the source(s) of serum proteins in the fœtal circulation *vis-à-vis* such passage Since the serum proteins of the mother may be considered to be in a steady state while their amounts in the fœtus are continuously changing, some measure of the synthesis by the fœtus is desirable and even necessary for an investigation of the passage of similar proteins from the mother into the fœtus The present investigation was undertaken to measure fœtal synthesis of serum proteins and to examine the passage with the aid of isotopically labelled serum proteins , some preliminary results are reported here

Fœtal synthesis Dutch rabbits were opened under anæsthesia at the end of 24 days of gestation and each fœtus was given an intraperitoneal injection of 50 μc of lysine labelled with carbon-14 (specific activity 1 mc /mmole) through the uterine wall At various intervals after injection, one or two fœtuses were removed and fœtal blood was collected from the heart Maternal blood was also sampled at various times The serum samples were divided into 50-μl aliquots, one of which was planchetted and counted on an end-window Geiger counter Another aliquot was precipitated with an equal volume of 10 per cent trichloroacetic acid (TCA) and a known volume of the supernatant was counted In some cases the precipitate was washed with 5 per cent TCA, dissolved in 0 1 N sodium hydroxide and counted on a planchette Whenever possible, two other aliquots were electrophoresed on paper (Whatman No 1, barbiturate buffer of *p*H 8 6 and ionic strength 0 1, and 30 m amp of constant current for 16 h) One paper strip was stained in bromophenol blue after the run and the other was cut across into 5-mm wide pieces These pieces were placed in planchettes and counted in a modified windowless Geiger counter There was good agreement between counts in the TCA precipitate above and the total counts on paper

Data on the incorporation of lysine into serum proteins, for 24 h after injection, were thus obtained and curves were fitted manually The maternal curve rises very slowly with time and reaches a plateau at about 14 h after injection, but the fœtal curve rises very steeply, reaches a peak at about 3 h and declines gradually to less than a fourth of the peak value by about 12 h after injection

The rate of incorporation, obtained from the initial part of the fœtal curve, is 350 c p s per ml of serum per hour The specific activity of fœtal serum proteins at the peak of incorporation is 840 c p s per ml of serum The total protein concentration of 24-day fœtal sera, estimated by the Biuret method[3], is 22 1 mg per ml of serum Assuming that the incorporation of lysine labelled with carbon-14 indicates synthesis of proteins $\left(\frac{840}{22\ 1 \times 350} = 0\ 11 \text{ mg/h}\right)$, 2 64 mg of total serum proteins are synthesized by the fœtus during the 24 h, that is, the 25th day of gestation This is clearly a minimum figure, underestimated by possibly as much as 20 per cent, since the specific activity at peak incorporation only approximates the maximum value attained by serum proteins It is noteworthy that this peak value is achieved in the fœtus in less than a quarter the time taken by the mother

Fig 1 shows the distribution of the incorporation of labelled lysine into the various serum proteins Duplicate electropherograms, one stained and the other estimated for radioactivity, show counts corresponding to albumin and α-, β- and γ-globulins It is interesting to find that the relative distribution of counts corresponds closely to the relative percentages of these protein fractions in 24-day fœtal serum and are different from those of maternal serum

Passage from the mother into the fœtus Dutch rabbits (2 3 to 2 7 kg) were given 0 25 – 1 0 mc of cystine (specific activity 1 mc /mmole) and bled 8–12 h later About 6 per cent of the administered activity was incorporated in the total serum proteins of the animal and 69–73 per cent of the total serum activity was in the TCA-precipitable fraction

About 30 ml of this labelled serum was injected intravenously into a 19 day pregnant rabbit and the fœtuses were sampled 3½–4 h later Less than 1 per cent of the maternal serum concentration of protein-bound activity was found in fœtal serum proteins and about 0 2 per cent in the protein of amniotic and allantoic fluids

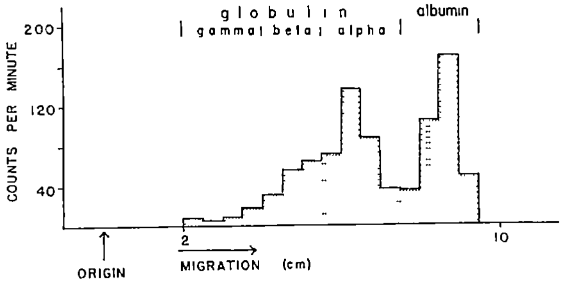

Fig 1 Distribution of radioactivity among serum proteins synthesized by the 24–25 day old rabbit fœtus The fœtus was given ^{14}C-lysine intraperitoneally Forty μl of fœtal serum was electrophoresced in duplicate on paper, one strip was stained for proteins and the other counted

In order to determine whether maternal serum proteins pass to a greater extent into older fœtuses, 10–12 ml of labelled serum were given intravenously to 24-day pregnant rabbits Samples obtained 11 and 22 h after injection showed that the protein-bound activity in fœtal serum was 2 per cent of that of the maternal serum at 11 h and 17 per cent at 22 h The amniotic fluid and stomach contents of the fœtus showed about 1–2 per cent of the protein-bound activity present in an equal volume of the maternal serum

There seems to be no doubt that increasing amounts of protein are passed into the fœtus with advance in time after injection and at advanced stages of gestation[3]

Winkler *et al* [4] used iodinated rabbit serum albumin to study passage in albino rabbits in the last week of gestation The activity of iodine-131 in fœtal serum at 16–24 h after injection appeared to indicate passage, however, the activity of fœtal samples was considerably reduced by dialysis or on electrophoresis of the serum

In our passage experiments, electrophoresis of fœtal serum followed by localization of radioactivity on the paper strip, indicated at least three peaks of activity coincident with the albumin and α- and β-globulin bands The fœtal stomach contents showed only two peaks of activity, in the albumin and γ-globulin regions.

This investigation was begun in 1957 and was supported by grants from the Office of Naval Research *Nonr* 233 (40) and the Atomic Energy Commission, No *At*-04-1-*Gen*-12

Suppression of Tuberculin Reaction in the Scorbutic Guinea Pig

In a recent publication from this laboratory it was noted that vitamin C deficiency in guinea pigs prevented induction of experimental allergic encephalomyelitis as well as development of the tuberculin reaction[1]. Replacement of the scorbutic diet with a normal stock diet four weeks after deprivation began and three weeks after inoculation of the challenge vaccine containing brain and killed *Mycobacterium butyricum* in water-in-oil emulsion permitted subsequent development of tuberculin sensitivity although the guinea pigs failed to develop clinical or histological signs of experimental allergic encephalomyelitis. It was important to determine the exact basis for the animals' failure to respond to tuberculin by development of a skin reaction because of the bearing this information might have on the induction of experimental allergic encephalomyelitis. Did absence of vitamin C prevent the end organ response (development of a positive skin reaction to tuberculin or, in the case of experimental allergic encephalomyelitis, the inflammatory lesions in the brain), or was the vitamin essential to the primary immunological response to the injected antigen(s)?

It is known that a generalized state of delayed hypersensitivity can exist in animals which fail to give a positive skin reaction, for example, tuberculous rabbits may lose their cutaneous hypersensitivity without decrease or loss of cellular hypersensitivity[2]. The present communication shows that the skin of the scorbutic animal is capable of responding to tuberculin if the delayed hypersensitivity has been induced prior to deprivation of vitamin C. Thus we can assume that the inhibition of the response comes from interference with the actual induction of delayed hypersensitivity rather than interference with the skin's reactivity.

Disease-free, mixed-colour, male guinea pigs, bred in a closed colony in the Animal Production Section at the National Institutes of Health, were used for all experiments described. Their weights were 400–500 gm. They were obtained from a stock colony one week prior to inoculation of tuberculin and maintained on the diet specified. All animals were maintained in large general-purpose cages, six to a cage, on a bed of sawdust and cedar shavings.

Tuberculin sensitivity was induced in the guinea pigs by one intracutaneous injection of 0.1 mgm *Mycobacterium butyricum* (Difco) in 0.1 ml. of an emulsion made up of one part phenol–saline (0.5 per cent phenol–0.9 per cent sodium chloride), one part melted 'Aquaphor' (Duke Laboratories), and two parts mineral oil (Fisher Scientific Co.).

The 'normal diet' consisted of stock diet for guinea pigs (N.I.H. Formula *A*) plus a daily supplement of greens, cabbage and kale. Vitamin C-deficient diet was supplied by Nutritional Biochemical Corporation. The guinea pigs on the 'scorbutic diet plus vitamin C' received 50 mgm. ascorbic acid (Lederle) daily in 0.1 ml. intraperitoneal injection. All animals received tap water *ad lib*.

Tuberculin sensitivity was measured as mm. induration 24 hr. after intradermal injection of 0.1 ml. of second-strength tuberculin (0.05 mgm./ml.).

All animals were placed on their respective diets, as indicated under diet I in Table 1, for a week prior to inoculation with *M. butyricum*. The skins were tested two weeks after inoculation and, after these tests, the guinea pigs were placed on their second diet. The second skin test was performed three weeks after institution of the second diet.

Table 1. SUPPRESSION OF TUBERCULIN RESPONSE IN THE GUINEA PIG BY VITAMIN C DEFICIENCY

Diet I	Diet II	No. of animals	First tuberculin response mm. induration (mean ± S.D.)	Second tuberculin response mm. induration (mean ± S.D.)
Normal	Normal	6	10.7 ± 2.1	12.8 ± 2.1
Normal	Scorbutic	8	10.3 ± 2.3	11.9 ± 1.4
Scorbutic plus vitamin C	Scorbutic	6	11.0 ± 4.4	9.3 ± 2.9
Scorbutic	Scorbutic plus vitamin C	5	0.4 ± 0.2	7.6 ± 2.0

Guinea pigs were put on diet I one week prior to injection with Freund's complete adjuvant (0.1 mgm. *Mycobacterium butyricum* ID). Two weeks after the injection they were challenged with 5 μgm. tuberculin and the skin reaction observed 24 hr. later (first response to tuberculin). Each group was then placed on diet II, and after three more weeks again challenged with 5 μgm. tuberculin (second response to tuberculin).

As shown in Table 1, the animals on the vitamin C-deficient diet, when inoculated with *M. butyricum*, failed to respond to tuberculin as in the previous investigation[1]. Also, as had been observed previously, restoration of vitamin C to these animals resulted in subsequent development of sensitivity to tuberculin. In the present series of animals, the second tuberculin test was carried out only three weeks after the vitamin C supplementation was instituted. This was possibly too short a time for the animals to recover completely from their scorbutic state, since the skin reactions observed were somewhat less pronounced than the reactions of animals on the normal diet. There was no difference in the first tuberculin response of animals on a normal diet and the response of animals on the scorbutic diet plus vitamin C injections. Removal of vitamin C from the diet after the hypersensitive state had been induced did not alter significantly the tuberculin response (line 2 in Table 1).

From these results it would appear that the vitamin C-deficient guinea pig is able to respond dermatologically to tuberculin once tuberculin hypersensitivity has been induced. Failure of the induction of the delayed hypersensitivity phenomenon itself would appear to be the best explanation for the absence of response to tuberculin in those animals which were on the vitamin C-deficient diet at the time they were inoculated with *M. butyricum*.

Age Differences in Cyclic Motor Reaction

DIFFERENT manifestations of time judgment in man, becoming still more important with the advent of flights into space, have been examined by a vast number of psychologists as well as psychiatrists[1], and last but not least by physiologists, including those of the Pavlovian school[2]. They used methods of estimation of presented intervals, production and reproduction of intervals, and finally methods aiming at revealing the mechanism of time judgment itself I examined the motor reproduction (tapping) of intervals of 5 sec during 120 sec after a training period of 60 sec in each experiment The results are given in Table 1

Table 1 ACCURACY AFTER 120 SEC OF REPRODUCING 5 SEC INTERVAL

	Women (13) (aged 20–30)	Men (4)	Girls (18) (aged 10–14)	Boys (26)
Accurate (within ± 2 sec) (%)	10 56	6 67	2 63	2 44
Shortened ('overestimated') (%)	23 94	20 00	52 63	58 54
Prolonged ('underestimated') (%)	65 50	73 33	44 74	39 02
No of experiments in group	286		120	

Sex differences are as yet not considered with regard to numeral inhomogeneity of the groups reported

Frolov[3] claims that in adults shortening of intervals prevails and he assumes that this 'overestimation' represents the prevalence of inhibition in the equilibrium of the two main neural processes My results do not support this hypothesis unless it is accepted that in groups of children inhibition prevails, which is not probable On the contrary my results are in accordance with the findings of Hormia[1], who also quotes experiences that tendency to 'underestimation' gradually rises with age In some other way my point of view is supported by the finding of lengthening intervals, reproduced verbally, in narcosis (Robson *et al* [4]) Holubář[5] observed a preceding reaction during conditioning of time-reflex, I observed the same, but only in children, during 60-sec training of the tested interval

To explain his findings, Frolov considers the trace reflex to be the underlying pattern of the motor reproduction of intervals, Hull[6], on the contrary, considers this category of performance as conditioned reflex to cyclic phase My own explanation agrees more clearly with Hull the command for the motor reaction might cause, as usually accepted, a focus of excitation in the brain, and in the case of preliminary set-up delay motor realization is inhibited for the time necessary Lack of inhibition would then result in a preceding motor reaction, its dominance over excitation would cause delayed reaction

Lipid Metabolism in *Astacus astacus* (L.)

ALTHOUGH not all vertebrate classes have been examined with regard to lipid metabolism, it has been established that vertebrates are able to synthesize cholesterol from acetate by way of squalene Sometimes this phenomenon has been generalized for invertebrates However, this view has proved to be incorrect A wide variety of insects have been found to require cholesterol as an indispensable component in their food[1–3], and it has therefore been suggested that insects cannot synthesize their own sterols, but rather modify the steroid nuclei present in their food It has been shown that the carnivorous beetle *Dermestes vulpinus*[4] is incapable of incorporating carbon-14 of fed 1-^{14}C-acetate into squalene or cholesterol The same has been found for the bluebottle *Calliphora erythrocephala* (Meig)[3] In Annelida, it has been found that mevalonic acid is converted into squalene by *Lumbricus terrestris*[5], but the cyclizing of this hydrocarbon to a sterol could not be demonstrated The work recorded here is concerned with the possible biosynthesis of cholesterol in *Astacus astacus* (L)

Table 1 ACTIVITY OF LIPIDS IN *Astacus* INJECTED WITH 1-^{14}C-ACETATE

	Counts/min
Crude lipids	286 7±5 4*
Fatty acids	262 0±6 0
Saturated fatty acids	397 6±5 1
Unsaturated fatty acids	205 9±2 8
Unsaponifiable fraction	145 7±2 0
Wax-like substances from the unsaponifiable fraction	135 0±0 8
Crude squalene	4 7±1 0
Squalene hexahydrochloride	0 1±0 0
Cholesterol-digitonide	0 4±0 0
Cholesterol	–0 02±0 02

* *S E*

During autumn, ten animals (in the intermoult stage) were injected four times at intervals of 48 h Each dosage consisted of a volume of 0 4 ml containing 4 mg of 1-^{14}C-sodium-acetate (activity 2 5 μc /mg)

After a period of eight days the animals were killed by freezing at −20° C They were dehydrated with ethanol, dried and exhaustively extracted with ether in a Soxhlet apparatus The ether extract was evaporated to dryness in a stream of nitrogen and yielded 3 0313 g of lipids

In order to remove the unsaponifiable fraction from the residue the lipids were saponified with alcoholic potassium hydroxide The non-saponifiable fraction was extracted with ether and yielded 0 5309 g of a solid mass after evaporation in a stream of nitrogen

The fatty acids were isolated from the saponified fraction and separated into saturated and unsaturated fatty acids by lead salt fractionation The unsaponifiable fraction was extracted many times with portions of petroleum ether (b p 60–70° C) From the extracted substances 0 2350 g (probably wax-like compounds) appeared to be insoluble in petroleum ether

The petroleum ether solution was chromatographed on alumina After 150 ml petroleum ether had passed through the column, most of the squalene proved to have been eluted The elution was continued with 100 ml of benzene and finally with 150 ml of ether to remove the sterols[6] The petroleum ether fraction yielded 27 5 mg of crude squalene A sample was used for isotope analysis To the remaining 15 6 mg, 15 1 mg carrier squalene was added and the hexahydrochloride was prepared according to Heilbron's method as modified by Loud and Bucher[7]

The ether contained 220 6 mg of crude sterols from which the cholesterol was isolated with digitonin It was removed from the digitonide with pyridine

From the various fractions samples were burned to carbon dioxide, which was precipitated as barium carbonate The activity was determined with a Geiger–Muller tube, under the conditions of infinite thickness According to Calvin *et al* [8] these activities are proportional to the specific activities and therefore comparable

The results given in Table 1 show that *Astacus astacus* (L) can convert acetate into fatty acids but not into squalene and cholesterol

The labelling of the saturated fatty acids is about twice as high as that of the unsaturated fatty acids This is in agreement with the results obtained in vertebrates and points to the formation of the unsaturated from the saturated fatty acids

PHARMACOLOGY

Catecholamine Metabolism in Morphine Withdrawal in the Dog

I have noted[1] a decrease in the catecholamine content of the rat brain after withdrawal of chronic administration of morphine This finding, however, seemed to be confined to a certain strain of rats with very conspicuous abstinence symptoms, while an increased urinary excretion of adrenaline and noradrenaline[2] was observed in three different rat strains For studies of abstinence phenomena of the excitatory type, comparable with those found in man, higher species must be studied In 1932 Tachikawa[3] reported an increased amount of 'adrenaline' in the blood of chronically morphine-treated dogs when the drug was withheld In 1960 and 1961 Maynert and Klingman[4,5] reported a decrease of brain and adrenal catecholamines in morphine-tolerant dogs and rabbits when an abstinence syndrome was produced by nalorphine No numerical data were given for the decrease

The present work deals with the effects on catecholamines in brain, adrenals and urine of dogs, during induced morphine tolerance and subsequent abstinence

After an acclimatization period, the 24-hr urines of 4 saline-injected dogs weighing 3–5 kgm were collected daily in separate metabolism cages during 5 days, before the morphine injections were started (control-levels) The effect of one subcutaneous injection of nalorphine was then recorded The excretion of catecholamines was also recorded in the beginning of the daily morphine injections 2 months later when morphine had been given in doses increasing from 3 to 100 mgm /kgm /day the effect of nalorphine (10 mgm /kgm) was studied on the morphine-tolerant animals Finally the effect of abrupt withdrawal was followed for 3 weeks

Urinary catecholamines were estimated according to Euler and Lishajko[6] Recovery experiments yielded 64–72 per cent (mean 68 per cent) for added amounts of adrenaline and 65–75 per cent (mean 71 per cent) for noradrenaline No corrections were made for these losses

Twelve young dogs out of three litters, each weighing 4–10 kgm, were used Ten were treated with daily injections of morphine hydrochloride for about 2 months and two dogs were untreated controls 24 hr after a final morphine dose of 100 mgm /kgm the ten animals were divided in two groups Five dogs received saline injections and the other five received two doses of nalorphine 10 mgm /kgm 2 hr. apart Two hours after the last injection the animals were killed by a shot through the heart The brains were dissected out immediately and the adrenals 15 min later The brains were divided into 3 portions (1) telencephalon, (2) cerebellum, (3) brain stem (excluding the central nuclei belonging to 1) They were treated by the method of Bertler *et al* [7], but the final determination of catecholamines was made on a Coleman fluorimeter. The telencephalon was also analysed for the content of dopamine according to Carlsson and Waldeck[8] Recoveries (means of 6 experiments) were: adrenaline 85 per cent, noradrenaline 92 per cent and dopamine 87 per cent The adrenals were extracted with 5 per cent trichloroacetic acid and, after dilution in appropriate amounts of *N* sodium acetate buffer at *p*H 6 5, determined for catecholamine content like the urine eluates Recovery adrenaline 98 per cent, noradrenaline 95 per cent

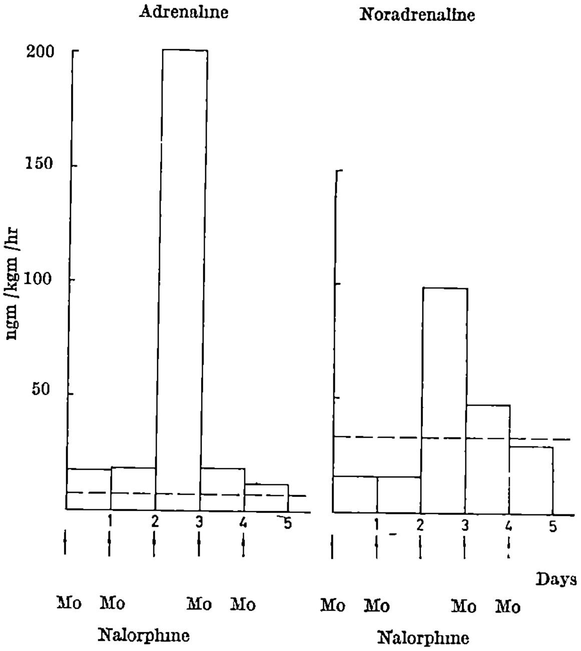

Fig 1 Daily urinary excretion (means of four animals) of adrenaline (left) and noradrenaline (right) in dogs made tolerant to 90 mgm./kgm of morphine hydrochloride daily On the third day the morphine injections were replaced by nalorphine 10 mgm / kgm Broken horizontal lines represent mean levels of the same animals when untreated during a preceding control period

Arrows indicate daily injections

During the control period the urinary excretion of noradrenaline was 31 6 ± 1 9 ngm /kgm /hr and adrenaline 7 8 ± 0·8 ngm /kgm /hr (means ± $S E$ of 20 observations) Administration of 10 mgm /kgm of nalorphine hydrochloride did not influence the noradrenaline-level, but increased the adrenaline excretion on the day of injection to 37 5 ± 10 0 ngm /kgm /hr. ($P < 0 01$) The urinary excretion of adrenaline and noradrenaline rose as a result of injection of 3 mgm /kgm of morphine hydrochloride daily and returned to the normal range within ten days on the same dose The same pattern reappeared when the dose was increased to 6 mgm /kgm in accordance with the findings in rats[2] Two months later when the animals were receiving 90 mgm /kgm of morphine daily the substitution of morphine by

Table 1 NORADRENALINE (NA) AND DOPAMINE (DA) IN THE BRAIN, ADRENALINE (A) AND NA IN THE ADRENALS (MEANS $\pm S$ E) OF DOGS TREATED WITH MORPHINE (Mo) IN DOSES INCREASING FROM 3 TO 100 MGM./KGM. FOR TWO MONTHS AND THE EFFECT OF NALORPHINE-INDUCED ABSTINENCE

		Telencephalon		Brain stem	Cerebellum (ngm /gm)	Adrenals (μgm /gm)

5	Mo 2 months Nalorphine 10 mgm /kgm × 2	88±9 8**	191±33	219±26 7**	52±6 4**	552±137**	160±32

** Significance-level for difference between saline- and nalorphine-treated animals $P < 0$ 01

one injection of 10 mgm /kgm nalorphine resulted in a very marked increase of adrenaline for one day, while the accompanying increase of urinary noradrenaline persisted for a few days when the morphine injections had been reinstituted (Fig 1) When the morphine injections were abruptly withdrawn there was a sharp rise of the adrenaline excretion (mean of the maximal levels was 119 ± 20 ngm /kgm /hr reached on the second and third days) followed by a more delayed and moderate increase of noradrenaline (mean 87 ± 11 ngm /kgm /hr , the highest levels reached on the 3rd–6th day after withdrawal) This is in good accordance with the findings in rats[2]

Table 1 summarizes the effects of nalorphine on the catecholamine content of brain and adrenals There was a significant decrease of catecholamines in both organs and in all parts of the brain, and there was noticed an especially pronounced decrease in the animals which had the severest abstinence symptoms

Effect of 'Busulphan' on the Fœtal Gonad

BOLLAG[1] first reported that pregnant rats given an injection of 'Busulphan' 5–7 days before parturition produced sterile offspring Later, Galton and Till[2] stated that "earlier in pregnancy quite large doses do not interfere with its course and the F[1] and F[2] generations are apparently healthy" In view of these studies and our knowledge of the effect of 'Busulphan' on the adult rat testis[3–5], it was decided to re-investigate the sensitivity of the proliferating cell systems of the fœtal gonad during development

Rats were given a similar injection of 'Busulphan' in arachis oil (10 mg/kg, intraperitoneally) at selected times between the 5th and 20th day of pregnancy, the day sperm were found being regarded as day 0 A proportion of each litter was killed on days 1 and 15 *post partum* and the remainder at 6 months In the 1-day-old male, the drug effect on the gonocyte population of the testis was assessed and in the 15-day and 6-month-old rats the subsequent effect on spermatogenesis

After an injection on day 5 or 7 *post coitum* the 1-day-old neonatal gonad appeared normal A marked increase in the number of seminiferous tubules containing no sex cells ('sterile' tubules) was observed in animals treated on day 9 , it approached 100 per cent following injection between days 11–14 inclusive (Fig 1) After administration of 'Busulphan' on day 18 or 20 of pregnancy the testis appeared normal at 1 day *post partum* Nevertheless, the 15-day gonad demonstrated that the drug had in fact prevented the subsequent development of the germinal epithelium This observation implies that there is a lag of several days between administration of 'Busulphan' and its destructive effect on the gonocyte population

An attempt is being made to determine (*a*) the extent of the regenerative capacity of the testis , (*b*) to what extent histological damage can be correlated with fertility Histological studies on the testes of 6-months-old rats are at present incomplete The adult material examined so far shows that the percentage of 'sterile' tubules rises from approximately 15 per cent after exposure *in utero* on the 11th day to nearly 100 per cent after exposure between the 14th to 16th days inclusive Following treatment on the 11th day of gestation 65 per cent of tubules were 'sterile' in the 15-day *post partum* testis, and it is

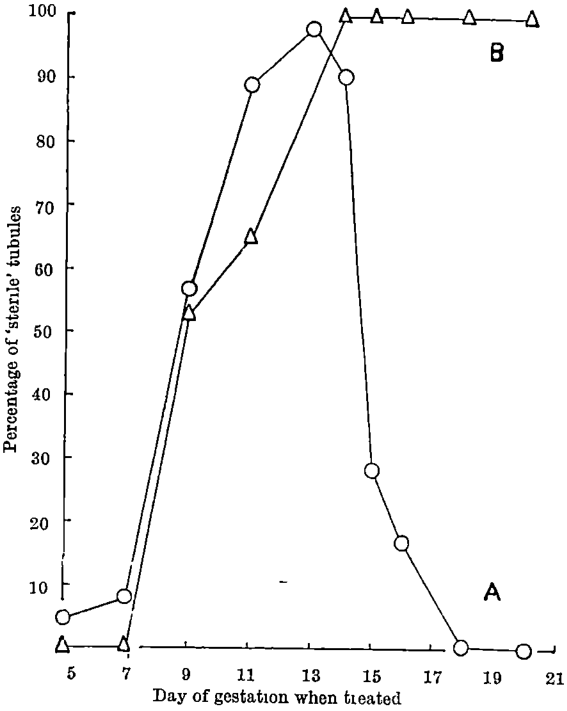

Fig 1 Curve *A* indicates the results found in the 1-day *post partum* testis and curve *B* the results at 15 days *post partum* Each point on the curves is a mean value from 3 offspring, and is based on a count of 1,800 seminiferous tubules counted in transverse section Tubules were classified as normal or 'sterile', the latter containing only supporting cells

suggested that the diminution to 15 per cent in the adult testis is the result of the regenerative capacity of the organ. So far it appears that animals are fertile following treatment on or before the 11th day, but sterility is the rule following treatment later in gestation.

These investigations demonstrate that the sensitivity of the gonocyte population to 'Busulphan' increases rapidly in pregnancy from about implantation. There is practically total destruction of these cells by injection of 'Busulphan' on or after 13 days *post coitum*. The failure of the gonocyte population to regenerate contrasts with the response of spermatogonia type *A* to the same treatment in the adult testis. Certain of these latter cells are known to be selectively suppressed for several weeks by 'Busulphan' at the same dose-level, after which recovery occurs[4,5]. We have previously emphasized the sensitivity to this substance of the early spermatogonial cell in the adult male rat and this clearly applies to its precursor, the gonocyte. At the same time, it is interesting that the number of other actively dividing cells within the tubules, the Sertoli cell precursors, appears to remain unaffected. As in the adult testis there is a differential sensitivity of proliferating cells within the fœtal gonad.

Work on day-old female offspring has shown no subsequent effect on the oocyte population after previous exposure to 'Busulphan' on either day 5 or 7 of gestation. A decrease in the number of oocytes occurred in the 1 day *post partum* ovary following drug administration between 9 and 16 days of gestation. Primordial oocytes were not seen in 15 day *post partum* ovaries from animals treated between days 13 and 16 of pregnancy, both inclusive. The effect was less marked after injection on day 9 while the drug appeared to have no action when administered on days 5, 7, 18 or 20 of gestation, that is, the 15-day *post partum* ovary was histologically normal.

The action of 'Busulphan' in the ovary therefore seems limited to the gonocytes, that is, precursors of the oocytes, and that when the gonocytes enter meiotic prophase on the 17th day of fœtal life, a notable decrease occurs in sensitivity to the drug. In spite of the homogeneous appearance of the gonocyte population during the 13th to 16th day of gestation, the results of treatment with 'Busulphan' during this time suggest that the cells exhibit a differential sensitivity to this compound. Some are able to continue development into oocytes and become associated with follicular development in the pre-pubertal animal. These follicles become atretic. Other gonocytes, the precursors of oocytes which will undergo development in the adult animal, are damaged by the drug. This will account for the absence of oocytes in the adult ovary.

The work is being extended to other related alkylating agents which have been shown to produce different effects on spermatogenesis.

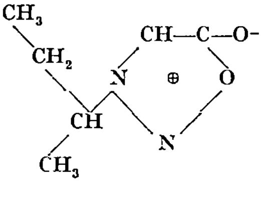
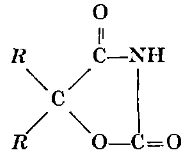
A New Class of Central Nervous System Stimulants

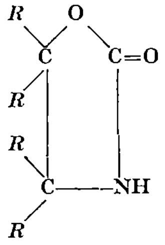
ALTHOUGH the mesoionic compounds called sydnones have been known and studied for some time[1], there have been no pharmacological studies reported on the ring system. A closer examination of the sydnone ring reveals a rough similarity to the rings of 2,4-oxazolidone (II) and 2-oxazolidone (III).



(I)



(II)



(III)

These are anticonvulsants, however, if the nitrogen atoms of both are alkylated with fairly long chains, the action is often reversed, leading to a convulsant compound[2]. Accordingly, a series of new *N*-alkyl sydnones have been prepared and the pharmacology studied.

Compound (I) was synthesized as follows: secondary butylamine in dry ether in the cold was treated with one half equivalent of ethyl bromoacetate in dry ether by slow addition. After standing overnight, a 35 per cent yield of ethyl (*sec*-butylamino) acetate was distilled at 57°/0.4 mm (found: N, 8.90). The amino-ester was then hydrolysed to the amino-acid in refluxing base for 5 h. This compound was then treated *in situ* with acid followed by a 30 per cent solution of sodium nitrite, slowly introduced at 0°. After standing overnight, a 65 per cent yield of *N*-nitroso-*sec*-butylamino-acetic acid was filtered off, m.p. 79°–80° (found: N, 17.26). The nitrosoamino-acid was then refluxed 3 h with acetic anhydride and then allowed to stand in the dark for three days. The excess anhydride was removed under vacuum and a 67 per cent yield of a straw-coloured oily 3-*sec*-butyl sydnone was distilled at 160°/3 mm (found: N, 19.96), refractive index at 20°, 1.4928, λ_{max} (ethanol) 290 (E-6300).

The LD_{50} of (I) injected subcutaneously in male brown mice ($C57B \times 1101$ hybrids) was calculated by the methods of Litchfield and Wilcoxon[3] as 135 ± 9 mg/kg and the convulsive dose as 117 ± 13 mg/kg. Pentylenetetrazole under the same experimental conditions was calculated as LD_{50} 75 ± 3 mg/kg. The convulsions beginning in less than 1 min after administration of compound (I) produced ticking in the facial musculature and fore-limbs. This was followed by clonic movements which frequently developed an extensor component. Almost all the animals died in tonic convulsions. Although a few deaths were recorded on the fifth day, these calculations were based on mortality-rate in 72 h

A spinal cat, transected at *C*-1, showed no convulsive activity in dosage to 100 mg/kg A decerebrate cat showed a definite convulsive pattern at 200 mg/kg

When 41 mg/kg of either (I) or pentylenetetrazole was administered intravenously to a dog given sufficient pentobarbital sodium intravenously to cause apnœa, a more favourable respiratory response and rise in blood pressure, following the transient fall after administration of either, was obtained with (I)

The respiratory stimulation of (I) appeared to be predominantly central as there was little decrease of activity after vagotomy or denervation of the carotid sinus

The compound did not potentiate acetylcholine and produced no acetylcholine esterase inhibition[4] There was no antispasmodic activity against acetylcholine or histamine on the guinea pig ileum[4] No spasmodic activity was noted in isolated tissue although a positive Straub test[5] was observed in mice injected with (I)

Chemically, compound (I) differs importantly from (II) and (III) in that the ring is aromatic in character, possessing a sextet of electrons in association with all of the atoms comprising the ring[6] Further experiments in this laboratory have indicated that other compounds of this type possessing alkyl or aromatic-alkyl groups at position 3 and alkyl groups at position 4, on the carbon atom, are equally if not more active and less toxic We are at present synthesizing and pharmacologically evaluating an extensive series of these compounds

HÆMATOLOGY

Absorption-Elution Method of Grouping Blood-Stains

Based on an examination of eleven blood-stains, Schleyer has published a critique of the absorption-elution test[1] Since my own experience is so completely at variance with Schleyer's, this note is written with the purpose (*a*) of recording statistics based on the examination of approximately 600 blood-stains of both experimental and actual case material (*b*) of pointing out where Schleyer's procedure is, on his own description, markedly different from that recommended by Kind[2,3]

Testing experimental blood-stains of known group Some 400 blood-stains of known group have been tested in this Laboratory, mostly in duplicate, since the introduction of Kind's method These experimental groupings (in which anti-A, anti-B and anti-H sera have been used) were carried out on blood-stains made on filter paper and cotton cloth, or as dried aqueous extracts[4] The age varied from a few minutes to several years In every instance the proper and expected reaction has taken place agglutinations were unequivocal and easily visible to the unaided eye These tests on blood-stains of known group were performed on every occasion when unknown case material has been grouped in order to provide controls

Testing case material of unknown group These total more than 200 (again, mostly in duplicate), and are recorded as in Table 1

Table 1

	1959	1960	1961
No of groupings attempted	35	64	125
No of successful groupings	10	35	98
Percentage successful	29	55	78

The method was adopted in early 1959 and used for selected cases Since 1960 I have used it exclusively for antigen testing The improvement in the percentage of successful results stems from many causes, but a major factor was, I feel sure, the increasing experience of the operators The causes of failure are only too well known to the serologist with practical experience, for example, inadequacy of sample, the presence of grease, dirt and absorbing substrata Although the test is basically very simple, it will not tolerate too much arbitrary variation The substratum has, in the main, been cotton and woollen cloths, but has included paper, wood, leather, steel, soil and vegetation 'Successful grouping' in Table 1 is intended to mean a clear-cut macroscopic result which has been confirmed in most cases with the results obtained from agglutinin tests[5]

Variations in the technique introduced by Schleyer

(1) The indicator cells used by Schleyer in testing for anti-A elution are A_2, whereas Kind recommends A_1 A_1 cells are more sensitive than A_2 cells as an indicator of anti-A elution

(2) Glass slides with 12-mm cavities are recommended for the test Schleyer uses spotting tiles The greater thermal capacity of the tiles will tend to retard the heating of the test suspension in the moist chamber and consequently a longer elution time will be required

(3) The original paper[3] specifies that 30 μl of 2 per cent red cell suspension should be added to individual cavities before elution Schleyer uses "a few drops" Undue dilution of antibody will diminish the final agglutination intensity

(4) Although gorse (*Ulex europeus*) is suggested as a source of anti-H, Schleyer uses *Laburnum alpinum Watereri* The lack of result using this reagent suggests a low titre of the extract Anti-H extracts should be discarded if the titre is less than 1 in 128 (ref 6) As the final agglutination intensity is, in part, dependent on the amount of antibody elution, it is of importance to use an antiserum of adequate strength

(5) Schleyer uses a lens to read all his results, after transferring the agglutinates to slides Kind mentions that a microscopic examination may be necessary for thinner smears, but this procedure is exceptional In practice I find recourse to the microscope unnecessary and the tedium of constant pipetting is avoided Only clear-cut results are accepted, all others are rejected

(6) I experience no difficulty in distinguishing between A_1 and A_2 stains, nor do I note any practical

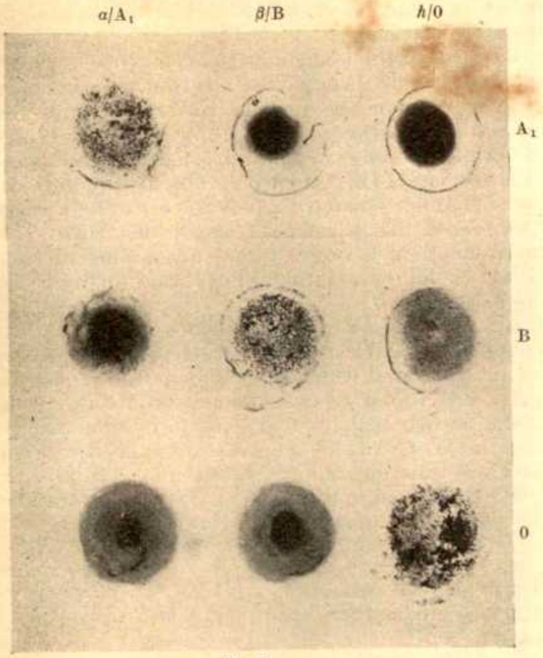

Fig. 1

differences between grouping fresh and old stains, although, of course, blood-stains gradually become insoluble and more difficult to extract.

Table 2 presents reactions for the various groups, and Fig. 1 shows typical test results.

Table 2

	α/A₁	β/B	h/0
A_1	+	−	−
A_2	+	−	+
B	−	+	(+)
A_1B	+	+	−
A_2B	+	+	+
0	−	−	+

PATHOLOGY

Virus-like Behaviour of Human Carcinoma

A THOROUGH study of 20 autopsy cases of metastatic carcinoma to liver[1,2] and kidney and of 72 cases of primary carcinoma of the liver (hepatoma)[3,4] has revealed the following facts:

(1) Continuity of structurally normal parenchyma with contiguous cancer parenchyma (Figs. 1 and 2). This was observed in 30 per cent of hepatoma cases in the liver and in 100 per cent of metastases to the liver and kidney. This higher percentage of positive findings in the material which promised less probability for this finding is ascribed to more careful sampling of blocks for sectioning.

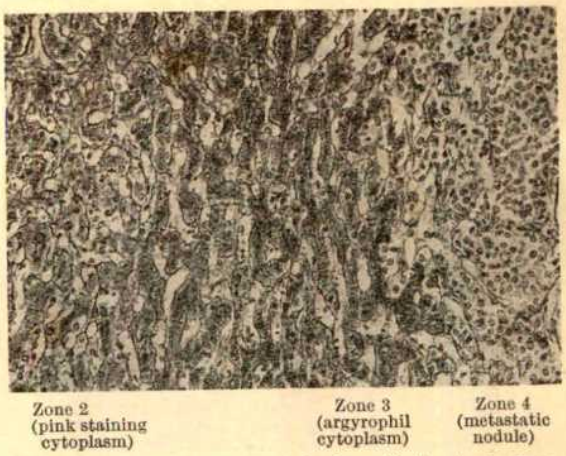

Fig. 1. Metastasis of a carcinoma of vulva epithelium to the liver

(2) Presence of single cancer cells in the vicinity of tumours as integral components of the host parenchyma, under conditions where invasion could be excluded (Fig. 3).

(3) Morphological evidence for transformation of normal cells into cancer cells.

(4) Transformation is preceded by cytochemical changes not visible with routine stains, but recognizable if special stains are applied.

A typical tumour nodule is surrounded by roughly concentric zones of structurally normal parenchyma. From outside in, one can distinguish four zones characterized by typical staining reactions of their cytoplasm. In Table 1, the colours of the zones are

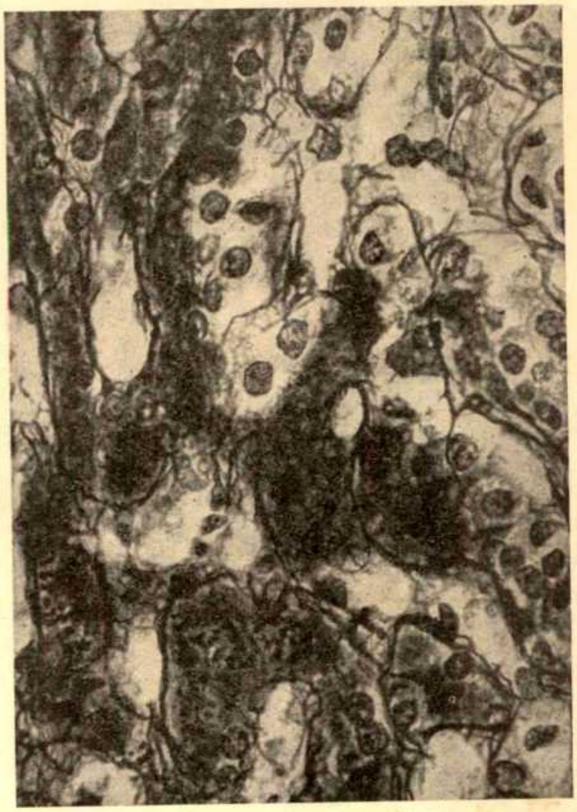

Fig. 2. Detail from Fig. 1 showing continuity of cancer parenchyma with liver

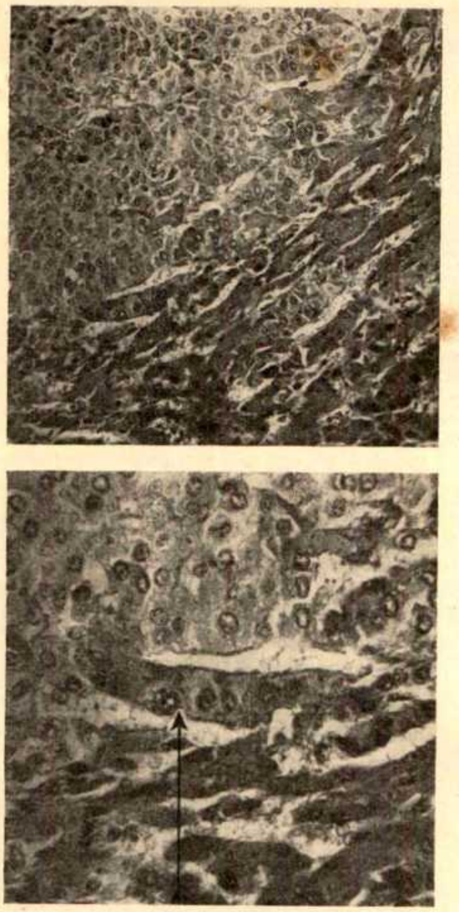

Fig. 3. Marginal area of a hepatoma (Bantu). Below, details from above figure. Arrow indicates cancer cells within a liver plate

described as they appear: (*a*) when stained with hæmatoxylin and eosin; (*b*) when impregnated with uranium and silver according to Wilder[5]; (*c*) when stained with acridine orange and observed with the fluorescence microscope according to Schuemmelfeder's method[6], as modified for paraffin sections by Abrams and Elias[7]. Zones 2, 3 and 4 are easily seen in Fig. 1.

With the acridine orange method the nuclei of all cells, whether malignant or normal, known to contain DNA, fluoresce red-orange, a fact which led to the following virological explanation of malignant transformation.

Let us assume hypothetically that the genome of a certain chromosome in every cancer cell contains one abnormal gene (a DNA molecule) which causes the cell to act as a cancer cell, and which also causes its own mass replication.

Table 1. COLOURS OF CYTOPLASM

	Hæmatoxylin and eosin	Wilder's uranium and silver impregnation	Acridine orange fluorescence
Zone 1 (zona sana)	red	pink	green
Zone 2 (zona affecta)			deep yellow
Zone 3 (zona determinata)		black or dark grey	
Zone 4 (zona maligna)	blueish purple	colourless clear or light grey	red orange

Replicas of the malignant gene leave the nucleus of the cancer cell through the electron microscopically visible pores in the nuclear membrane and, while present in the cancer cell cytoplasm, cause both its red-orange fluorescence and its slight basophilia.

These large DNA molecules break up into components small enough to penetrate through the cell membrane. These relatively small constituents of the malignant gene fluoresce yellow but are invisible after hæmatoxylin-eosin staining or uranium and silver impregnation.

However, close to the tumour, where the concentration of these particles is greater, they form aggregates within or around which silver precipitates.

The argyrophil particles penetrate into the nucleus of the normal cell. A few of them become incorporated into one of the chromosomes in the original position, thus imparting 'genetic information' to the invaded nucleus. As soon as the incorporation is completed, the normal cell has become a cancer cell.

Cytotoxicity of Human Malignant Effusions

A COMMON objection to the more widespread use of human ascitic fluid as a growth medium is its frequent cytotoxicity, the nature of which is not well understood. Several investigators have described an antibody-complement system lethal to mouse cells, which is often present in normal human serum[1-3] and also in sera of some other species[3]. It is not demonstrable in human cerebrospinal fluids though[4].

The objective of this investigation was to determine whether a similar antibody system could be found in human malignant effusions, and if so, to compare its effect on mouse cells and human cells. In addition, the influence of various means of inactivation on the growth-promoting capacity of the fluids was examined.

Six samples of ascitic fluid were obtained from patients with malignant effusions, who had not had any medication for at least 4 weeks. Each sample was divided into 4 parts which were processed as follows: (1) no treatment; (2) heated at 52° C for 30 min to inactivate C′2 of complement; (3) incubated for 1 h at 37° C with 'Zymosan' (1·5 – 2·0 mg/ml. of ascitic fluid) to inactivate C′3 of complement; (4) incubated with mouse fibroblasts (Earle's strain *L*) for 1 h at 4° C (10^6 cells/ml. of ascitic fluid) to remove *L*-cell specific antibody while complement remains active.

After treatment, all four types of ascitic fluid were centrifuged at 2,000 rev/min for 20 min, and stored at −20° C up to the day of use.

Experiments were performed on strain *L* cells, strain *C*-4 human carcinoma cells[5] and a 3-months-old culture of human fibroblasts, which had been established in this laboratory. All cells were maintained on Waymouth's medium *MB*752/1, supple-

Each value represents the mean ± *S.E.* of 6–8 cultures.

mented as follows: for strain *L*, 5 per cent calf serum; for *C*-4 cells, 10 per cent fœtal calf serum, 10 per cent umbilical cord extract and occasionally 5 per cent ascitic fluid; for human fibroblasts, 10 per cent fœtal calf serum, 2 per cent umbilical cord extract and 0·05 per cent lactalbumin hydrolysate.

Trypsinized cell suspensions were divided into 5 parts, centrifuged, and resuspended in the following five media: (*A*) Control: maintenance medium. (*B*) Four ascitic fluid media: 60 per cent Waymouth's medium and 40 per cent of ascitic fluid treated by the 4 methods described.

Inocula of 50,000–70,000 cells in 1·0 ml. of medium were distributed among screwcap tubes. The cells were allowed to grow for one week, and then the total cell mass per tube was determined by the colorimetric method of Grady *et al.*[6]. In addition, cell growth in each tube was graded microscopically on a + to ++++ basis; this grading always confirmed the colorimetric results. Also, cell clumping was noted and graded + to +++.

Five of the six samples of ascitic fluid were toxic to *L*-cells (Table 1), and in each case both inactivation of the complement and adsorption on *L*-cells resulted in a highly significant increase in cell growth ($P < 0·01$). Cell death and lysis took place in untreated fluids. Clumping was fairly marked in heated and 'Zymosan'-treated fluids but negligible after adsorption. No similar pattern was found in experiments on homologous cells (Tables 2 and 3). However, two of the procedures used for inactivation repeatedly altered the quality of the growth media to a statistically significant degree: preheating impaired subsequent growth of *C*-4 cells in three instances (Ran, Haw, Hop) and of human fibroblasts in one case (Lep). This was associated with clumping and poor adhesion to glass of the *C*-4 cells, but not the fibroblasts. Also, the use of *L*-cell adsorbed fluid resulted in significantly improved human fibroblast growth in four cases; no such effect was noted in *C*-4 cultures.

It may be concluded that an antibody-complement system lethal to mouse cells occurs in human malignant effusions, but that this system had no effect on the homologous cultures tested, of which one was fibroblastic and one epithelial. The prevention of clumping of *L*-cells by preceding adsorption suggests polyvalency of the antibody involved. Similarly, the cytotoxic antibody in human serum is not bound by human cells, and seems to be at least divalent[7].

The detrimental effect of heating on homologous cell growth may be of a similar nature to that described for serum by Weiss[8], namely, the impairment of adhesive activity due to destruction of heat-labile α-globulin. This would explain the absence of this effect on *L*-cells, since they can adhere to glass even in protein-free media. There is no explanation at present for the enhancement of human fibroblast growth by adsorbed fluids.

The striking difference in response among all 3 cell types to modifications of malignant effusions indicates the extent to which experimental results can be influenced by such factors, and the importance of using natural growth media in their optimal form for specific cell populations.

I thank Dr. S. Fedoroff for advice.

RADIOBIOLOGY

Protective Effect of Nitrous Oxide against Total-Body Radiation in the Mouse

IT has been shown that nitrous oxide and certain inert gases reduce oxygen-dependent radiosensitivity in broad bean roots and mouse Ehrlich ascites tumour cells *in vitro*[1]. Irradiation in one atmosphere of 80 per cent nitrous oxide with 20 per cent oxygen markedly reduced the radiosensitivity of mouse ascites tumour cells, as judged by chromosomal damage at anaphase. In a later investigation[2], using a different criterion of tumour growth after a standard inoculum of cells irradiated *in vitro* into normal animals, protection was not afforded by this nitrous oxide–oxygen mixture at 1 atmosphere pressure. Data have not yet been presented on a protective effect at elevated pressure. They demonstrated that xenon, the most effective of the inert gases in reducing oxygen-dependent radiosensitivity, was protective only at pressures in excess of 1 atmosphere in these *in vitro* systems.

A few investigations have been reported on the use of nitrous oxide–oxygen mixtures at 1 atmosphere on irradiation damage *in vivo*. Various unpublished results have been summarized[3] which suggest that no protection, as measured by lethality in the mouse from total-body irradiation, could be shown by these gas mixtures, and that the protective effect was due solely to the experimental conditions of the *in vitro* studies.

We have been investigating the protective effects of nitrous oxide and the inert gases in mixture with oxygen as measured by lethality in mice from whole-body irradiation and find that nitrous oxide does give significant protection at elevated pressures.

As shown in Table 1, two different strains of mice were used. In the initial study *CBA* mice from our own colony, both males and females, were irradiated at 8 weeks of age. Prior to irradiation, these mice were randomly distributed among the various experimental groups when removed from their litter; following irradiation, mice from the different experimental groups were mixed to eliminate 'caging effect'. The animals were exposed in an aluminium pressure chamber at 2 atmospheres pressure. The mice were exposed in groups of six while confined within plastic cylinders through which the test gas entered the chamber. By thus limiting movement, the dose variation from head to tail of the mice was diminished to ± 4 per cent. The irradiation was with 200 kVp at a quality sufficient to give a dose variation of ± 20 per cent dorso-ventrally. A commercially mixed tank of nitrous oxide and oxygen requested to contain 20 per cent oxygen, but on analysis in our laboratory by gas chromatography found to contain only 17 per cent oxygen (pO_2 130 mm mercury), was used. This mixture at 2 atmospheres pressure gave a highly significant reduction in 30-day lethality, as compared with groups in air at 2 atmospheres. Note in group *A* that a similar 30-day lethality is produced by 15 per cent lower radiation exposure when the air pressure is raised from one to two atmospheres. At least part of the protection in this group may be due to the slight reduction in oxygen tension from air at 2 atmospheres.

Two additional groups of mice have now been run on a mixture with guaranteed analysis of more than 20 per cent oxygen with 80 per cent nitrous oxide, which by gas chromatography in our laboratory was found to contain 20·36 per cent oxygen (measurement made by Dr. H. Zauder). To eliminate the possible influence of œstrus on radiation lethality, only male mice of the *C57L/J* strain were used in this experiment. Group *B* in Table 1 were approximately 10 weeks of age and were exposed to 750 r. measured at the centre of the mouse chamber, which was an LD_{50} (30 days), in air (at 2 atmospheres pressure). Group *C* were closer in age to the *CBA* group; approximately

Table 1

Strain (group)	Age	Sex	Gas	Pressure (atm)	pO_2	Radiation exposure	Lethality (31 days)	Significance	Anæsthetic deaths*

* Included in 30-day lethality.

† Includes one death during exposure from asphyxia due to twisted position in chamber.

‡ 1·2 mgm. pentobarbital intraperitoneally 15 min. before irradiation.

8 weeks, and were exposed to 775 r. approaching an LD_{100} (30 days), if exposed in air at 2 atmospheres. In groups *B* and *C*, since we were unable to standardize age accurately in these mice from a commercial supplier, the mice were weighed on the day preceding irradiation and randomized in the experimental groups according to weight. There again is clear-cut evidence of protection from the lethality of total-body irradiation, which is more clearly demonstrated in the higher dose group.

We have made one attempt to rule out the possibility that this protection is due only to narcosis, with diminished tissue oxygenation, by subjecting groups of mice to a comparable level of anæsthesia with pentobarbital during irradiation in air at 2 atmospheres pressure. The pentobarbital was given at a dose of 1·2 mgm. to mice with an average weight of 24 gm. In air at one atmosphere pressure there was protection from the lethal effect of total-body irradiation. This is contrary to the findings of Paterson[4]. In air at two atmospheres pressure, there not only was no protection in either *CBA* or *C57L* strain mice, but actually a higher lethality in the group anæsthetized with pentobarbital. This was only of borderline statistical significance in the *C57L* strain. In all these groups, those animals dying during the radiation interval have been scored as deaths during the first 30 days following irradiation. These deaths were presumably due to respiratory arrest from the anæsthetic agent and were less than 4 per cent of the experimental group in both the nitrous oxide and pentobarbital series.

The mode of action of the anæsthetic gas in reducing oxygen-dependent radiosensitivity is unknown. Our investigation shows, however, that nitrous oxide does diminish radiation sensitivity *in vivo*, in the presence of adequate oxygen supply, if the gas mixture is at elevated pressure. The diminution of oxygen-dependent radiosensitivity by anæsthetic gases thus appears not restricted to particular *in vitro* systems and might be applicable to clinical situations by altering an adverse oxygen effect in tumour versus normal tissue sensitivity.

We thank Dr. B. N. Drolette for statistical calculations. This investigation was supported by a research grant No. *C*4685 from the National Cancer Institute, U.S. Public Health Service.

State of Binding of Natural Manganese in Human Cerebrospinal Fluid, Blood and Plasma

It was suggested earlier[1,2] that the physiological behaviour of microconstituents of the body might not be reflected in nutritional, enzymological or even 'physiological' experiments conducted exclusively with pure or synthetic forms of these agents. More specifically, investigations using manganese additives to diets or to enzyme systems *in vitro* had been quoted as an illustration of experiments that might not bear directly on physiological parameters[3]. The basis for the reservation lay with the suspicion that these manœuvres might not result in quantitative duplication of the chelates, postulated to be characteristic of individual tissues and foodstuffs, and that, on the contrary, they might create artefactual complexes as well. It was conceded, however, that the natural state of binding of this element had not been investigated and that its natural chelates remained largely putative.

Tentative support for the existence of natural manganese ligands was derived from experiments in which artificial isotopes of this metal were observed to become bound to intracellular organelles[4,5], to porphyrins[6,7] or to plasma protein fractions[8] of animals or man. However, artificial isotopes might be suspected to reveal unnatural metabolic patterns, since their chemical form, the time allowed for equilibration, and many other factors are variables in the evolution of the observed pattern. Therefore, investigations of the native, natural manganese isotope (^{55}Mn) were assigned exclusive pertinence to the study of the natural state of binding of this microconstituent.

The sensitivity and the high precision necessary for such work are met by neutron activation analysis. The method used here has been published separately[9].

At the outset we searched for manganese-containing pools of the body, the metal of which might be readily separable into micro- and macro-molecular fractions. Spinal fluid was intriguing because its minimal protein concentration might favour a non-protein-bound form of this element, provided of course, that it did contain measurable quantities of manganese. Since blood, plasma and serum are instrumental in the transport of this metal, they were also of interest to the present investigation.

All reagents tested during initial investigations contained significant levels of manganese, with the possible exception of an optical crystal of sodium chloride[8]. Also, contact with some metallic instruments increased the manganese contents of biological samples significantly[9,10]. Hence, reagents were avoided and, instead, a high gravitational field was applied for the sedimentation of macromolecular manganese under an ambient temperature of + 5° C. Concordantly, either platinum or non-metallic materials were used in the construction of needles, instruments and vessels. These awkward steps appear to be indispensable until contamination becomes controlled by the simpler methodology now under investigation.

Spinal fluid samples from seven humans contained manganese concentrations varying between 0·83 and 1·50 μgm./l. A given sample of spinal fluid generally contained about half the concentration of the corresponding plasma sample. In the one patient who was fed manganous sulphate, the spinal fluid concentration was 3·0 μgm./l., indicating that this concentration increased concordantly with that of the red cells, in contradistinction to the steady plasma-levels (*vide infra*). Centrifugation of spinal fluid at $11 \times 10^4 g$ (ref. 10) for 48 hr. yielded a supernatant fraction which was protein-free by nephelometry[11]. This fraction contained 93–94 per cent of the metal while the protein sediment contained the balance. The whole venous blood of 19 donors contained 8·6 to 14·5 μgm. manganese per litre and their plasma contained 1·83–3·10 μgm./l. Three samples of hæmolysed normal human red cells and four of fresh human plasma were subjected to the same centrifugation for periods of time up to 60 hr. In the case of the hæmolysates, the protein-free supernatant layers contained 3·9, 6·7, and 10·5 per cent respectively of the total manganese. Hæmolysates from the person who had been fed manganese sulphate for many months (blood manganese being 42·35 μgm./l. and plasma manganese 2·82 μgm./l.) contained 4 per cent of the total metal in the protein-free supernatant layers. In the cases of the four plasma samples, the protein-free fraction contained 4, 7, 15, and 25 per cent of the total plasma manganese on repeated duplicate analysis.

It is known that alkaline, oxygenated solutions of manganese yield slowly a sedimentable fraction, probably a hydroxide[13]. This was confirmed by means of high-speed centrifugation of solutions of manganese salts in 0·9 per cent sodium chloride, brought to *p*H 7·2 by means of sodium hydroxide: about 14 per cent of the metal could be sedimented after manipulations identical to those referred to here. Since the *p*H of spinal fluid becomes alkaline on standing (*p*H 7·8), and thus favours formation of hydroxide, the manganese in this fluid might have remained non-sedimentable by virtue of having become stabilized as one or more micromolecular chelates. As opposed to this deduction, it is also fair to assume that the manganese of blood and of plasma was sedimentable by virtue of being bound to the proteins rather than simply as a consequence of the formation of hydroxides, since the sedimentable portion was high indeed. This latter view is compatible with the experiments which showed $^{54}MnCl_2$ to become bound to specific receptors in blood and in plasma[6-8]. Hence, it is safe to assume that the protein-poor spinal fluid contains primarily micromolecular manganese chelates while the protein-rich plasma and blood contain primarily macromolecular complexes of this element.

As has already been pointed out, manganese-54 was found to become bound to different species of receptor sites in plasma as opposed to red cells: in the first a globulin[7] and in the second a hæm[5,6] incorporated the tracer. It therefore became germane to ascertain whether the receptor sites of the native, natural element were as dissimilar as those of the artificial one. To demonstrate a dissimilarity between receptor sites, proton competition experiments were performed with samples of plasma and of hæmolysate. Acidification of plasma with distilled hydrochloric acid (*p*H 4·3–4·5), followed by high-speed centrifugation, yielded protein-free supernatant fractions containing 85–100 per cent of the total manganese concentration in these samples. In striking contrast, acidified hæmolysates yielded protein-free supernatant fractions containing only 17–24 per cent of the concentration of the metal in the hæmolysates. These tests showed that plasma manganese is more readily replaceable by protons than is red cell manganese.

The result of the present experiments illustrates the existence of more than one chemical species of manganese in the body. Therefore, it is highly problematical whether *in vitro* additives of manganese (or of other co-factors for that matter) can duplicate exclusively natural chemical forms of as high a divergence as that revealed here. On the contrary, the natural manganese compounds themselves emerge as a promising subject for study.

This work was supported by the U.S. Atomic Energy Commission. It was presented in part at the forty-fifth annual meeting of the Federation of American Societies for Experimental Biology, Atlantic City, New Jersey, during April 10–14, 1961.

Estimation of Storage Life of Fruits

As long ago as 1924 Kidd[1] produced a "progress curve of fungal invasion" which was used by her and co-workers[2,3] for assessing the storage life of apples. Similar curves have been obtained by workers in the Division of Food Preservation, Commonwealth Scientific and Industrial Research Organization, for the development of physiological disorders in cool stored fruits (Fig. 1). We have found this relationship may be made linear, in each case, by transforming percentage disorder to a probit[4] and storage time to a logarithm (Fig. 2). In addition to the advantage of linearity for calculating estimates, this transformation shows storage life is log normally distributed. Since such a distribution has a wide occurrence it is probable that it will apply to other disorders.

The above observation leads to convenient methods of estimating mean storage life and its standard error. There are two approaches in storage experiments, namely: (1) use of one sample when each fruit may be assessed repeatedly during storage; (2) use of several separate samples when each fruit may be assessed only once. In the former the selected sample is

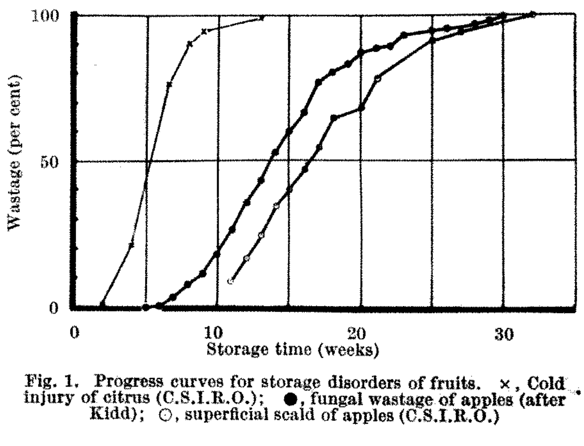

Fig. 1. Progress curves for storage disorders of fruits. ×, Cold injury of citrus (C.S.I.R.O.); ●, fungal wastage of apples (after Kidd); ○, superficial scald of apples (C.S.I.R.O.)

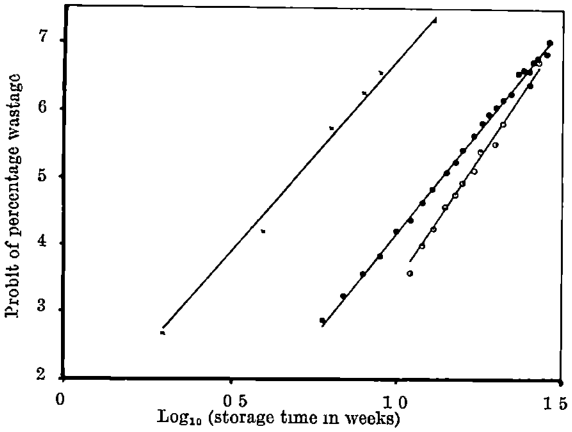

Fig 2 Data for storage disorders in fruits reduced to transforms giving linear relationship Symbols as for Fig 1

stored as a unit and the individual fruits examined periodically for development of disorder, the mean and standard deviation of storage life for the sample may be calculated as for any grouped data The latter situation, common in cool-storage experimentation, requires provision of a number of samples or units, each to be examined at only one of a series of times, this yields quantal data from which the methods of probit analysis provide an estimate of the log (time corresponding to a particular proportion of disordered fruit) together with its standard error

The probit method has been applied to data for superficial scald of Granny Smith apples in cool storage, to be reported in detail elsewhere

A Specific and Predictable Biochemical Anomaly in Interspecific Hybrids of *Baptisia viridis* × *B. leucantha*

In a chromatographic analysis of twenty-one putative hybrids of *Baptisia viridis* × *B leucantha* each of the hybrid types contained in the leaves 4 distinctive substances which were absent from the leaves of more than 25 specimens of each of the pure parental species examined The 4 hybrid-specific components were distributed in a novel pattern and reacted characteristically in ammonia vapour when observed in ultra-violet light Accordingly, they were considered to be bona fide hybrid-specific substances[1] Since there has been considerable interest in the appearance of new components in hybrids, and attendant theoretical implications touch on aspects of plant biochemistry and evolutionary mechanisms, it is important to establish conclusively that such substances actually are hybrid-specific and, if possible, their identity

As a result of a more comprehensive chromatographic study of *B viridis*, *B leucantha* and their natural hybrids we are now able to clarify somewhat the circumstances of the appearance of the 4 hybrid-type substances The same 4 hybrid-type substances occur as constant species-specific components of the flowers of *B viridis* The components are absent from the leaves of *B viridis* and entirely absent from *B leucantha* They are present in the flowers of hybrids of *B leucantha* × *B viridis* and in essentially unreduced amounts in the leaves of the hybrid While the substances cannot be considered as *de novo* products in the hybrid, they nevertheless are hybrid-specific in the leaf We wish to emphasize that these 4 components are major spots with unique attributes and they are consistently clearly identifiable in the circumstances described

B viridis also hybridizes with *Baptisia leucophaea* var *laevicaulis* and with *B nuttalliana*, but in these hybrids the 4 components are not detected in the leaves Of the 3 species with which *B viridis* hybridizes, *B leucantha* is most different both morphologically and, on the basis of present knowledge, biochemically Therefore, a greater genetic difference is probably represented in the hybrid, *B viridis* × *B leucantha*, and accordingly a breakdown in certain regulatory mechanisms is more easily explained in this hybrid We infer from the appearance of the 4 components of *B viridis* in the leaves of the hybrid *B viridis* × *B leucantha* that the mechanism which regulates the distribution of these components is disrupted so that the substances accumulate in sites in which they normally do not occur Presumably, the other crosses, which are thought to involve genetically closer species, do not result in as great a modification of leaf biochemistry

The interspecific hybrids of *Baptisia* generally contain the sum of the species-specific components of both parents, and most of the other components of the flower are present in the leaves as well[2] Therefore, it is not likely that a common precursor which is normally diverted in the leaves to form some other type of compound is available for conversion to the 'hybrid-type' components Certain properties of the 'hybrid-type' components indicate that they may be flavonoid in nature Thus, an abnormal build-up of these compounds could be analogous to that of the anthocyanin pigments in which a number of conditions deleterious to the plant as a whole encourage the formation of anthocyanin in atypical sites in the plant

It is possible that the phenomenon reported here could be used in artificial crosses with other species of *Baptisia* and *B viridis* to provide further knowledge of species affinities in the genus by a unique method Interspecific hybrids of *Baptisia* are unusually common Beyond this, the phenomenon cited falls into the category of examples which may at some future time provide an experimental tool for the analysis of genetic regulatory mechanisms operative indirectly on a biochemical pathway

An Inhibitory Growth Correlation in the Apothecial Stipe of *Sclerotinia sclerotiorum*

ALTHOUGH growth correlations have been widely studied in the higher plants, there have been few observations of this phenomenon in the lower plants, and none at all in the fungi The occurrence of such a correlation in the apothecial stipe of the fungus *Sclerotinia sclerotiorum* (Lib) D By , 1886, is described here

The *S sclerotiorum* used was isolated from a diseased bean pod of *Phaseolus vulgaris* from Spearwood, Western Australia, during September 1958

Under certain conditions of moisture and temperature, one to several stipes, 0 5–0 8 mm in diameter, may develop on the surface of sclerotia No external supply of nutrients is necessary for this to occur If the sclerotia and attached stipes are held in darkness, the stipes continue to grow in length without branching and may attain lengths up to 50 mm under laboratory conditions If their apices are exposed to light each develops a single apothecium

As extensive studies were being made on factors affecting the formation of apothecial stipes by sclerotia, germinating sclerotia were readily available The sclerotia formed by each culture had been air-dried at 25° C for 3 weeks, sterilized in 1 1,000 mercuric chloride, washed in distilled water and placed in a Petri dish containing 1 per cent water agar The dishes were then placed in a dark incubator at 15° C to induce the formation of apothecial stipes This usually occurred within six weeks

Twenty of the dishes were selected at random In each dish one sclerotium with an apothecial stipe more than 10 mm in length was located The apical regions of 1–2 mm were removed with a razor from ten such stipes The remaining ten stipes were left intact as controls The dishes were then partially sealed with 'Sellotape' to prevent desiccation and replaced in the incubator Observations were made weekly The experiment was repeated using 20 apothecial stipes longer than 20 mm , from half of which the apical 10 mm was removed

Decapitated stipes ceased to grow in length Lateral branches, morphologically similar to the parent stipe, developed in 1–2 weeks at lower levels on all except two such stipes (Table 1) The withering of the two stipes on which no branches formed probably resulted from damage to the point of attachment of the stipe to the sclerotium during decapitation Sometimes only one branch developed, but frequently several branches formed Occasionally, several formed at one point on the stipe In one or two instances, the apices of the lateral branches rested in water on the surface of the agar Such apices withered and branches formed on them at lower levels No branches developed on the intact stipes Under suitable light conditions all lateral branches, except the few which had withered, formed apparently normal apothecia at their apices (Fig 1)

Table 1 FORMATION OF LATERAL BRANCHES ON DECAPITATED AND INTACT APOTHECIAL STIPES

Treatment of stipes		No of branches formed per stipe									
		1	2	3	4	5	6	7	8	9	10
Experiment 1 (stipes > 10 mm long)	Decapitated (2 mm removed)	1	3	1	2	4	3	2	2	4	2
	Intact	–	–	–	–	–	–	–	–	–	–
Experiment 2 (stipes > 20 mm long)	Decapitated (10 mm removed)	3	3	–	6	1	2	4	5	–	2
	Intact	–	–	–	–	–	–	–	–	–	–

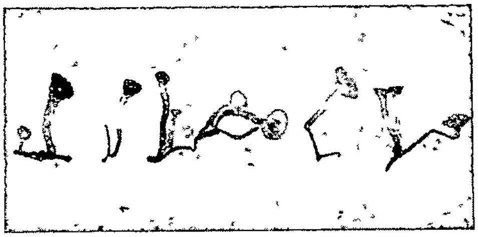

Fig 1 Mature apothecia at the apices of lateral branches on decapitated apothecial stipes The sclerotia have been removed Natural size

The origin of the lateral branches of the apothecial stipes of *S sclerotiorum* is uncertain They may originate from microscopic areas of meristematic tissue normally prevented from developing by the presence of the stipe apex However, no such areas were observed in the few longitudinal sections examined It is doubtful, therefore, if the phenomenon can be likened to that of apical dominance which occurs in higher plants It is more likely that they arose as a result of induced meristematic activity in mature cells following the removal of the stipe apex In this event the phenomenon would be one of regeneration comparable, for example, with the development of adventitious shoots below the cut end of decapitated hypocotyls in certain higher plants[2,7] Robertson[5] suggested that branching of the hyphal apex of *Fusarium oxysporum* following the arresting of the growth of the hyphal apex for more than 60 sec might be explained similarly

Auxins are thought to be involved in correlation phenomena in higher plants[1,6,7] However, though auxins are known to be produced by many fungi, they have not been assigned a growth-regulating role in these organisms[3] This may be because most experimental work has been concerned with the effect of auxins on growth of fungal mycelia rather than of fruit bodies The inhibition of the development of lateral branches by the intact apex of the apothecial stipe of *S sclerotiorum* may be determined to some extent by growth substances originating in the apex Certainly the apothecial stipe of *S sclerotiorum* appears to merit investigation as a source of growth-regulating substances in fungi

Germination of Resting Bodies in *Verticillium* Species

ALTHOUGH detailed investigations have been carried out on the morphology, physiology and pathology of *Verticillium* species, there are very few references to the function and germination of the resting bodies formed by these fungi Reinke and Berthold[1] drew diagrams of structures resembling germ-tubes emerging from resting mycelium but they gave no details Basu[2] and Van den Ende[3], working with *Verticillium* spp , failed to induce germination of microsclerotia Wilhelm[4] has stated that resting bodies of *V. albo-atrum* in diseased tomato tissue germinated by becoming covered with conidial heads This, however, does not directly prove, but merely implies, germination

In experiments to investigate the germination of resting bodies in *Verticillium* spp , we used the following species so that all types of resting bodies could be tested *V albo-atrum* forming resting mycelium, *V dahliae* forming microsclerotia, *V nigrescens* forming small chlamydospores, *V nubilum* forming large chlamydospores, and *V tricorpus* forming resting mycelium, microsclerotia and chlamydospores

Since resting bodies are difficult to separate macroscopically from the hyaline supporting hyphæ and conidia, a technique was developed whereby these structures could be dissected out under the microscope

In initial experiments, material containing resting bodies taken from 3/4 week-old cultures on Dox's agar medium was squashed in a drop of sterile distilled water between a glass slide and a coverslip and then spread on freshly poured nutrient agar in Petri dishes The preparations were then placed under the low-power objective of the microscope and the resting bodies separated from the surrounding material with a micro-needle operated from a Saunders-Singer micromanipulator[5], and placed in rows or in a series of squares marked out on the agar The plates were then incubated at 22 5° C in the dark for 12 hr Of all the resting bodies tested under these conditions, only the chlamydospores of *V nigrescens* germinated, giving 85–100 per cent germination The suggestion may be made, therefore, that the resting bodies of *V albo-atrum*, *V dahliae*, *V nubilum* and *V tricorpus* are dormant, according to the definition of Gottlieb[6], a "dormant spore is one which does not germinate under the same nutritive and environmental influences which later allow the production of germ-tubes"

Germination failed to occur also when the above technique was used together with the usual methods of breaking dormancy in fungal spores, namely, the addition of nutrients, vitamins, amino-acids, enzymes, detergents, soil extracts, root exudates and extracts from appropriate host-plants to the agar medium on which the resting bodies were spread, and alternate wetting and drying of resting body material in test-tubes, and passing oxygen over the resting structures on agar plates Heat-shock and treatment with sub-zero temperatures also failed to bring about germination

Germination did occur, however, when the above procedure was modified to allow for prolonged soaking of the resting bodies as follows after squashing the material containing resting bodies, a loopful of the preparation was transferred to 0 5 c c of sterile distilled water in 'Pyrex' glass tubes and incubated at 22 5° C in the dark for 12 hr A 0 1-c c sample was then spread on distilled-water agar in Petri dishes, the resting bodies isolated by micromanipulation and the plates incubated for a further 12 hr at 22 5° C in the dark Non-soaked resting bodies were used as controls

Germination achieved by the foregoing method was approximately 56 per cent for resting mycelium of *V albo-atrum*, while for *V dahliae*, whereas groups of cells from microsclerotia showed 75 per cent, single cells gave only 5 per cent germination Chlamydospores of *V. nubilum* gave 84 per cent germination In *V tricorpus*, it was assumed that the resting mycelium, microsclerotia and chlamydospores were randomized in the preparation and so all three types were included in the counts, which showed approximately 91 per cent germination Non-soaked controls showed no germination.

The low percentage germination of single cells of microsclerotia of *V dahliae*, as contrasted with clusters or groups of cells which may be part or whole microsclerotia, raises the question as to whether there is division of function between the individual cells of these resting structures, that is, whether some cells are destined to germinate whereas others are not, and serve some other function Although no distinct morphological distinction has yet been discerned between the cells, this problem is being further investigated

Prior to germination, hyaline granules appear in the resting bodies of all the species investigated In *V albo-atrum*, the individual cells of resting mycelium frequently become somewhat rounded, while in *V dahliae* the cells of the microsclerotia often become invaginated No swelling occurred, neither was any operculum or germination-pore observed in any of the resting bodies

During germination, one or sometimes two hyaline germ-tubes developed from all types of resting bodies, although not in any constant position

In *V albo-atrum*, these germ-tubes branched and produced conidia within 6 hr , whereas in the other species this occurred very much later

These investigations on the germination of the resting bodies may indicate their role in the survival of *Verticillium* species in the soil, and this is the subject of further studies

Longevity of Conidia of *Peronospora tabacina* Adam.

During the three years ending 1961, *Peronospora tabacina* Adam has spread from north-western Europe east to the U S S R and Turkey and south to Algeria and Tunisia The evidence[1] indicates that this extensive distribution has been brought about by dissemination of the thin-walled, almost hyaline conidia that are produced in very large numbers I have found up to 750,000 conidia per cm ^{2} of infected leaf surface, while Corbaz[2] records twice this number The effectiveness of conidia in initiating infections in previously free areas depends, *inter alia*, on their ability to survive during transfer Survival (viability) on glass slides to which water is afterwards added to obtain germination is favoured by low temperatures and low relative humidities[3], but with this procedure germination is extremely variable More recently, Cruickshank[4] and Shepherd[5] have shown that reliable data on germination of conidia can be obtained on agar.

In the experiments summarized in this preliminary report, conidia were produced on disks cut from leaves in the pre-sporulation stage[6] The disks were transferred to filter paper to remove excess water, then stored, at different relative humidities, in desiccators held at constant temperatures Disks were withdrawn, at intervals, from the desiccators, washed in water to remove conidia and a drop of the conidial suspension so obtained was placed on an agar block for incubation at 15° C for 24 hr Table 1 shows the period in days over which germination, down to as low as < 1 per cent, occurred in conidia stored at the stated temperatures and relative humidities, and, for comparison, the period of survival of approximately 15 per cent of the conidia

Table 1. LONGEVITY (IN DAYS) OF CONIDIA OF *P tabacina* STORED AT CONSTANT TEMPERATURES AND RELATIVE HUMIDITIES

Temperature (° C)	30		25		20		15		10		5	
Relative humidity (per cent)	*A*	*B*	*A*	*B*	*A*	*B*	*A*	*B*	*A*	*B*	*A*	*B*
80–100	0	0	2	2	9	7	6	6	12	6	12	8
70–80	0	0	5	3	9	7	21	14	30	22	46	36

40–50	0	0	10	6	—	—	43	27	—	—	—	—
30–40	–	–	21	7	36	20	75	43	106	70	131	90
20–30	–	–	29	10	69	22	—	—	—	—	—	—
10–20	–	–	42	7	106	40	22	19	—	—	—	—
Nominal nil	3	0	5	1	13	2	15	2	20	2	20	2

A, <1 per cent survival, *B*, approximately 15 per cent survival

The results confirm the earlier conclusions of Angell and Hill[3] They also show that optimum longevity of conidia at all temperatures did not occur at the same relative humidity As temperature increases, optimum longevity occurs at lower relative humidities It is considered that under the dynamic situation imposed by temperature and relative humidity interaction, viability of conidia is conditioned by the balance established between transpiration and respiration If the results are considered in terms of water potential, which is regarded as identical with diffusion pressure deficit, then it can be shown that maximum longevity at all temperatures occurs at approximately the same low water potential value

Thus conidia have a remarkable capacity for survival under the dry conditions characteristic of the regions in which *Nicotiana* spp , the natural host plants, occur In general, it would appear that dry, hot conditions such as may occur in field or glass-house cannot be expected to eliminate conidia as a factor in spread of *P tabacina*

Distribution of Certain Strigeid Trematodes in Great Britain

THE genus *Apatemon* has been recorded frequently from members of the Anatidae in Europe and the United States[1,2] In Britain only one published record of this genus seems to be available Baylis[3] recorded *Apatemon gracilis* (Rudolphi, 1819) from *Anas penelope* from Cheshire Two unpublished records exist of the occurrence of this species in Wales Davies[4] described this species from a domestic duck, and Williams[5] recovered 12 specimens of *Apatemon gracilis* (Rudolphi, 1819) from *Anas crecca* and 15 specimens from *Anas penelope* The host–parasite lists of Nicoll[6] are not considered valid in this context as they do not differentiate between European and British records

Over the past eight years, parasitological studies on the invertebrate fauna of freshwaters in Glamorgan (South Wales) have shown the larval stage of this genus to be quite widely distributed in leeches (particularly *Erpobdella*) and in snails, especially *Lymnaea pereger* (Fig 1) Collections of leeches from Breconshire (Llangorse Lake) and Radnorshire have also been found to be infected The rate of infection of *Erpobdella* varies from approximately 12 per cent for Llangorse Lake to roughly 90 per cent for Roath Park Lake, Cardiff At a recent vacation course in parasitology at Windermere, one (*Erpobdella octoculata*) out of four species of leech was found to carry *Apatemon* metacercariæ A total of 194 *Erpobdella octoculata* from three different habitats (Lake Windermere, Drunken Duck Tarn and Clea Barrow Tarn) were examined, and the percentage infection for the total collection was 30 per cent All three habitats were infected, and the highest single infection-rate was at Windermere where approximately 50 per cent of the leeches were infected The numbers of metacercariæ varied from 1–13 and a sample of 26 infected leeches yielded 144 metacercariæ At the end of the course, 200 *Erpobdella* from Windermere were brought back to Cardiff and fed to helminth-free, 16-day-old ducklings The ducklings were killed on the 15th and 18th day after infection (exps 88 and 89) and adult *Apatemon gracilis minor*, Yamaguti 1933, recovered In the same way samples of the metacercariæ from South Wales leeches have also been correlated with *Apatemon gracilis minor*, Yamaguti 1933 One of the adult populations obtained in this way[7] has its metacercaria in *Erpobdella octoculata* and its furcocer-

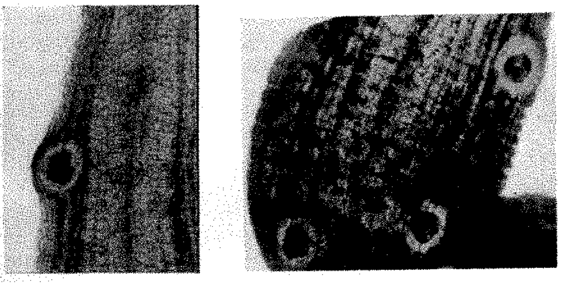

Fig. 1. *a*, A superficial cyst, lateral in position in *Erpobdella octoculata*; *b*, A multiple infection with more deeply situated cysts. Note the hyaline cyst wall. The cysts are easily observed in living leeches by compressing the leech between two slides and examining with a low power lens, using transmitted light (both × 21)

carial stage in *Lymnaea pereger*. Another variety (*Apatemon gracilis pellucidus*, Yamaguti 1933), also obtained experimentally in the duck[8], has its metacercaria in the body-cavity of bullheads (*Cottus gobio*) present in the streams near Cardiff. Thus there seems to be a fairly abundant reservoir of *Apatemon* metacercariæ in fresh-water leeches and snails, although the frequency of the occurrence of this genus does not seem to be reflected in the lists of adult trematodes recorded from birds in Britain. The reason for this may be in the short adult life of *Apatemon*, which under experimental conditions in the duckling seems to survive for only three weeks. This brief life-span would reduce the chances of its recovery from a natural population of birds.

The metacercaria of *Diplostomum phoxini* (Faust, 1918) parasitic in the minnow has been recorded from many parts of Scotland[9,10] and from the Aberystwyth area[11] in Wales. Samples of minnows from Windermere and Grasmere showed an infection rate of 100 per cent and 65 per cent respectively with a diplostomulum-type metacercaria. In both cases the metacercariæ were free in the posterior ventricles of the brain and sometimes occurred in the spinal cord. Material sent to Cardiff and fed to 1-month-old helminth-free herring gulls produced a heavy infection of *D. phoxini* (Faust, 1918) adults (Expt. 92). The life-cycle of this species has been described by Rees[12] and a longifurcous, pharyngeal cercaria resembling that described by Rees has been obtained from *L. pereger* in Windermere. Unfortunately not enough material was obtained to allow a complete morphological description and an experimental proof of its identity.

I thank the Director and his staff at Ferry House, Windermere, for facilities.

Note added in proof. Since this communication was submitted for publication the records of I. C. Williams have been published (*Ann. Mag. Nat. Hist.* (13), **4**, 467 (1961).

ENTOMOLOGY

Structure of the Micropyle in Eggs of *Nasonia vitripennis*

IN insects a micropyle is formed at the anterior pole of the egg and often has a very complicated structure. Sometimes it is a single pore or it may consist of numerous canals grouped together. The formation of the micropyle is due to a number of follicle cells or nurse cells having protoplasmic prolongations towards the egg, around which the chorion is secreted[1]. Snodgrass[2] pointed out that although a micropylar area is present in the egg of *Apis mellifera* no actual pores have been demonstrated. There is no published work on the structure of the micropyle in chalcids.

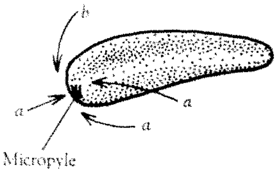

Fig. 1. Egg of *Nasonia vitripennis*

The eggs of *Nasonia vitripennis* (Walker) (Hymenoptera, Pteromalidae) are of a typical hymenopterous shape, like that of a curved sausage but more pointed at one end than the other. They are formed in polytrophic ovarioles, and the pores in the chorion which constitute the micropyle are the result of protoplasmic strands from the trophocytes and are situated at the rounded end of the egg, farther away from the oviduct end of the ovariole.

The ovaries were dissected from 50 specimens of *N. vitripennis* and, having been stained with aceto-orcein, were made into temporary mounts and examined with a light microscope. This, therefore, entailed examination of 100 ovaries each with four ovarioles, and each of these with one or two eggs showing micropyles, the total number of eggs being 480.

Owing to its curvature, each egg has in its meridional plane a convex and concave side. The micropyle is invariably situated in a slightly sub-apical position on the concave side of the meridional plane (Fig. 1). It consists of five radiating grooves in the chorion of the egg which narrow as they converge. Each of these grooves leads into a tube which narrows as it passes through the chorion and opens to the egg beneath by a pore (Fig. 2). The grooves radiate over an angle of 270° of arc from the centre of the micro-

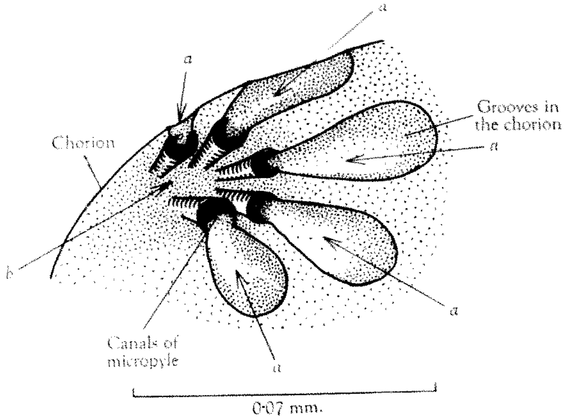

Fig. 2. Micropyle

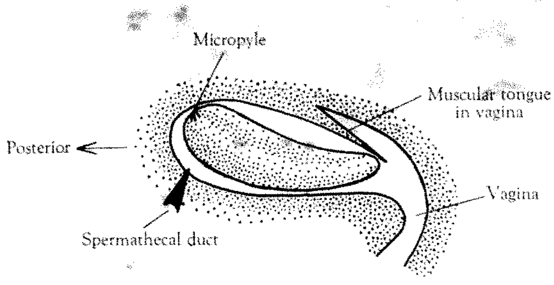

Fig. 3. Egg passing through uterus, with convex meridian orientated ventrally

pyle. The other 90°, which is situated on the convex side of the meridional plane of the egg, has no grooves.

When a population of *N. vitripennis* has ready access to host puparia, so that the parasites are not resorbing their eggs, each generation of offspring has a sex ratio of about three females to one male, the letter derived from unfertilized eggs[3]. Within each ovariole the eggs are orientated so that the oldest eggs (those nearest the oviduct end) have their convex sides pointing away from the axis of the ovary[4]. The spermathecal duct in *N. vitripennis* opens into the postero-ventral surface of the vagina in the mid-line, and it has been suggested that when eggs enter the vagina with their concave face either ventrally or laterally orientated the spermathecal duct can make contact with the micropyle allowing the sperms to enter the egg (Fig. 1*a*), but that when the egg has its convex face ventrally orientated (Fig. 3) the spermathecal duct is remote from the micropyle and fertilization much less likely. The structure of the micropyle would help this suggested mechanism of sex determination because if the spermathecal duct approaches a micropyle within an arc of 45° on each side of the convex meridian (direction *b*, Figs. 1 and 2) there would be no grooves there to guide the terminal portion or the discharge sperm towards the pores of the micropyle. The structure of the micropyle, in addition to providing a point in the chorion for sperm entry, helps to control the proportion of eggs fertilized and hence the proportion of females in the next generation.

I thank Mr. R. F. O. Kemp for help, and Prof. E. W. Knight-Jones in whose department this work was done.

Parallel Evolution in European and North American Populations of a Geometrid Moth

THE phenomenon of industrial melanism in the Lepidoptera has provided an exceptional opportunity for the observation of minor evolutionary changes within relatively short periods of time. Many species of moths, have, in the past 100 years or so, developed melanic forms which have spread and largely replaced the predominantly pale-coloured 'normal' forms. Melanic forms first appeared and have reached their greatest relative frequencies in or near centres of heavy industry. Selective predation by birds appears to have contributed toward the decrease in relative frequency of the original pale forms[1]. *Biston betularia* (L.) (Geometridae) is the species which has been most extensively studied in Britain, and since a very similar moth, *B. cognataria* Guenee, occurs in North America, some comparison of the evolution of melanism can be made. It can be assumed that geographical barriers prevent gene flow between North American and European populations of these moths.

Although *B. betularia* and *B. cognataria* are now regarded as distinct species, they may, in fact, be so similar genetically that they should be regarded as conspecific: no difference has been found in the structure of the male genitalia[2], and they will interbreed in captivity[1]. Even so, the pale forms of each are quite distinct: in *B. betularia* the wings are white, speckled with black, and the postmedial and antemedial lines are broken up into spots and blotches, while in *B. cognataria* the wings are much darker, more heavily speckled, and the postmedial and antemedial lines are clearly defined. The melanic forms are extremely similar in both species: the entire wings and body are black and the intricate pattern of the pale form is absent, except in a few specimens in which traces of the postmedial line on the wings can be distinguished.

In Britain, the first melanic *B. betularia* was recorded in Manchester about 1848[3], while in North America the first melanic *B. cognataria* was recorded in Philadelphia in 1906[4]. In many parts of Britain[1] and in some areas of north-eastern North America (for example, near Detroit)[4], melanics now comprise up to 90 per cent of the population. It appears that the spread of melanic forms began about 50 years later in North America than in Britain, but in both areas melanic forms first occurred, and are now at their highest frequency, in or near centres of heavy industry.

It is, of course, possible that the potentiality for producing melanic mutants was present before North American and European populations became isolated and that, until recently, selection has prevented their spread through the population. But the rapid changes in gene frequency which have occurred in North American and European populations of these moths have taken place independently in response to a similar environmental change: increased industrialization. Hence for the first time we have direct evidence of parallel evolutionary changes in isolated populations of moths. Evidently many other species of North American and European moths are being similarly affected, especially in such genera as *Phigalia* and *Ectropis*[4]. What happens in the future will be of considerable interest.

Mode of Host Selection by an Aphid

CONCLUSIVE evidence of the properties of plants which determine host selection in aphids has been lacking[1]. The host plants of the cabbage aphid, *Brevicoryne brassicae* (L), are restricted to the Cruciferae and Resedaceae[2] in which mustard oil glucosides are characteristically present[3] and known to stimulate feeding by certain lepidopterous larvæ[4]. To test the

Table 1. BEHAVIOUR OF *B. brassicae* DURING THE FIRST 10 MIN AFTER ARRIVAL ON THE SHADED SIDE OF HOST (*B. rapa*), NON-HOST (*V. faba*) AND SINIGRIN-TREATED NON-HOST LEAVES

	Time spent on shaded side of leaf (sec)	Total time spent probing (sec)
Brassicae rapa L.	600	444
Vicia faba L.	148	68
Sinigrin treated *Vicia faba* L.	580	470

effect of such a substance on *B. brassicae*, the mustard oil glucoside sinigrin was introduced into young leaves of the broad bean, *Vicia faba* L., which is not a host of this aphid. The leaves were set with the cut petiole in a 2 per cent aqueous solution of sinigrin for 2 h before and also during each experiment. Apterous virginoparous adult aphids were given a choice between such a sinigrin-treated leaf and a similar but untreated leaf, standing side by side under a 2 × 1 in. glass vial. 45 aphids were used in a total of five experiments. After 24 h an average of 93 per cent of the aphids were found settled and feeding on the sinigrin-treated leaf, with an average of four new-born larvæ each. Only two larvæ altogether were found on untreated leaves and the few adults seen there were restless. *B. brassicae* were reared on sinigrin-impregnated broad bean leaves continuously to the fourth generation when the culture was still healthy.

The time taken to show discriminating behaviour on a host or non-host substrate varies with the responsiveness and consequently the pretreatment given the aphid. To test the initial behaviour young virginoparous apterous adults were kept in plastic containers for 24 h in darkness and 10 min in light. The main act of host selection then occurred after a brief probe. When a leaf of turnip (*Brassica rapa* L.), which is a host of *B. brassicae*, was held upright and lit from one side only, and an aphid was led on to the shaded side where it received only the light transmitted through the leaf, the aphid made a brief probe. If during its subsequent movements it reached the edge of the leaf where it met the direct light, it turned back into the shade. Probes were repeated on the shaded side, and the aphid had often settled there in the feeding posture within 10 min. On a non-host such as broad bean, presented in the same way, the aphid again made a brief probe and walked to the leaf edge but, instead of turning back, continued over on to the illuminated side and walked off the leaf without further probing. Thus stimuli from the leaf determine the reaction to light. On a broad bean leaf presented in the same way but treated with sinigrin through the petiole, the aphids turned back from the edge and remained probing on the shaded side of the leaf exactly as if it had been a host leaf (Table 1).

These values are averages for 14 insects, each tested on the three leaves in turn.

That the sinigrin itself acts as the distinguishing stimulus was shown by means of disks of pith moistened either with a 0·2 per cent aqueous solution of sinigrin, or with water alone, both being covered with a thin celloidin membrane and lit with green light. As expected from Moericke's work[5], the green light was enough to induce one probe regularly, even on non-host surfaces. 27 aphids were each tested on both types of disk in the course of five experiments. The presence of sinigrin increased the average number of probes per aphid by 1·3 times and the average duration of a probe by 2·4 times. Similar results were obtained when 'Millipore' filters were used instead of pith disks.

In both the preceding experiments aphids discriminated only after probing. Further experiments with celloidin membranes showed that the essential stimuli were received via the stylets as they penetrated the substrate rather than externally by sense organs on antennæ, rostrum or tarsi. When aphids were tested as here on upright turnip and bean leaves which had been ensheathed in a thin layer of celloidin, the aphids discriminated between them clearly at once when the membrane was quite fresh. In a typical experiment all of 13 aphids tested walked off ensheathed non-host (bean) leaves within 3 min whereas all of 13 aphids were still on the unlit side of the ensheathed host (turnip) leaf after 10 min. This was not likely to be a response to material diffusing outward through the celloidin membrane because when similar discrimination tests were repeated at 5, 20 and 60 min after the membranes were applied there was no improvement in the response to the host. Nor did thickening the membrane reduce or delay the response. Furthermore, on broad bean leaves ensheathed and then treated externally with sinigrin the aphids displayed some tendency to turn back from the direct light at the leaf edge but did not settle. On leaves similarly ensheathed but treated with sinigrin through the petiole only, the aphids settled as readily as they did on the naked leaves so treated above. In fact, once the aphids could be induced to probe, they would settle down on a host leaf even when it was smeared with a substance such as crushed fennel leaf or clove oil which had a visibly repellent effect.

It is concluded that sinigrin is a specific stimulus for host selection by *B. brassicae*, and is received via the stylets after they have penetrated the leaf surface. A fuller account of this work and of the sense organs concerned will be published elsewhere.

I thank Dr. J. S. Kennedy for suggestions and discussion, Prof. V. B. Wigglesworth for granting facilities with the Agricultural Research Council Unit of Insect Physiology, and the National Research Council of Canada for a supporting grant.

MICROBIOLOGY

Chain Formation by *Phaeodactylum*

Phaeodactylum tricornutum (Bohlin) is a small marine diatom, with relatively unexacting growth requirements. Since the isolation of the original culture[1] several others have been started, and subcultures have been sent to many countries. The rate of growth in relation to nutrition and environmental conditions has been widely studied in unialgal and bacteria-free culture, as well as in mass culture. The species is also extensively cultured as food for rearing marine larval forms and filter-feeding invertebrates. Considerable speculation has centred on its taxonomic position[2].

Phaeodactylum is pleomorphic, producing ovoid, fusiform, triradiate, and cruciform cells[3]. A siliceous valve is possessed only by the ovoid form and that on one side only[4,5]. Despite its long history in culture, under a great variety of conditions, no mention has been made to date of chain formation by cells of this species.

During a routine examination of cultures maintained in this laboratory, it was found that *Phaeodactylum* had successfully invaded a declining culture of *Isochrysis galbana* (Parke) and was present as curved chains of up to 52 cells, as well as single cells. These chains consisted of either wholly fusiform or wholly triradiate cells, the component cells being of normal appearance and dimensions. The monotypic nature of the chains might suggest that the cells were dividing longitudinally, as do diatoms, replicating the original. No ovoid cells were observed in any of the chains examined. The exact medium conditions under which the chains arose are unknown, but they are persisting in heat-sterilized sea-water enriched with 0·8 p.p.m. phosphorus (disodium hydrogen phosphate) and 6·0 p.p.m. nitrogen (as ammonium sulphate).

I thank Mr. N. I. Hendey for assistance, and the Central Electricity Generating Board for financial support.

Streptomyces Species producing Oxytetracycline

Since the isolation of *Streptomyces rimosus*[1], a number of other species have also been described which produce the antibiotic oxytetracycline. The status of some of these species has been questioned[2,3], and comparative studies on induced mutants of *S. rimosus*[4] suggest that other members of this group might be naturally occurring variants. One recently described species, *S. albofaciens*[5], however, was stated to be distinct from *S. rimosus* as it produced a white aerial mycelium bearing numerous sporophores with monoverticillate spirals. The morphology of the sporophores is considered to be an important diagnostic character in the study of this genus, and if this culture falls into the section *Monoverticillus–Spira* of the scheme proposed by Pridham *et al.*[6] it would be far removed from *S. rimosus* and might even be placed in the separate genus *Streptoverticillium* Baldacci[7].

I have isolated independently two oxytetracycline-producing strains from soil which appear to be very similar to the described species *S. albofaciens*. The vegetative mycelium of the two strains is long and branching, penetrating the agar medium and also forming the tough, compact colonies which on certain media exhibit the wrinkles, folds and cracks characteristic of *S. rimosus*. The colonies are convex to umbonate and yellow to yellow-brown to golden-brown in colour, with a pale yellow-brown to brown soluble pigment diffusing into the medium. The aerial mycelium when present is coloured white to very pale grey. Both isolates show only sparse growth on Czapek's agar, moderate liquefaction of nutrient gelatin, only very slight peptonization of skim milk, good hydrolysis of starch and positive reduction of nitrate. They were also very similar to *S. rimosus* in the utilization of various carbon sources. They did, however, have a distinct aerial mycelium morphology.

The aerial mycelium of one of the isolates (*A*5279) was thin and limited almost entirely to very long hyphæ growing upright but usually forming a loose network with hyphæ from the same colony or adjacent colonies. Spore chains appear to be borne in whorls on these very long hyphæ, the individual chains in each whorl showing very irregular spirals or loose coils often encircling the main axis, so giving the aerial mycelium a beaded or knotted appearance when viewed under low-power magnification (Fig. 1). The actual structure of the individual whorls is difficult to determine owing to the coiling of the spore chains. Examination of extremities of the long hyphæ shows few whorls of two or sometimes three short and immature sporophores, arising from the same point or close together on the main axis, which become coiled during elongation to produce the typical knot-like structures. In most cases there appears to be only a single side branch which either coils several times around the main axis or branches almost immediately into two or three coiled secondary branches which fragment into spores.

The other isolate (*B*7648) shows the same gross morphological appearance as *A*5279. The aerial hyphæ are again very long and bear the sporophores in knots at intervals along their length. In this case, however, the whorl structure is less apparent, and sporophores are mostly single side branches, sometimes showing secondary branching, which again show the loose and irregular coiling.

This pseudo-whorl structure of the aerial mycelium in *Streptomyces* has been described previously for several species[8,9], and its more pronounced appearance in these strains (*A*5279, *B*7648, *S. albofaciens*) is related to the greatly extended main axis of the aerial

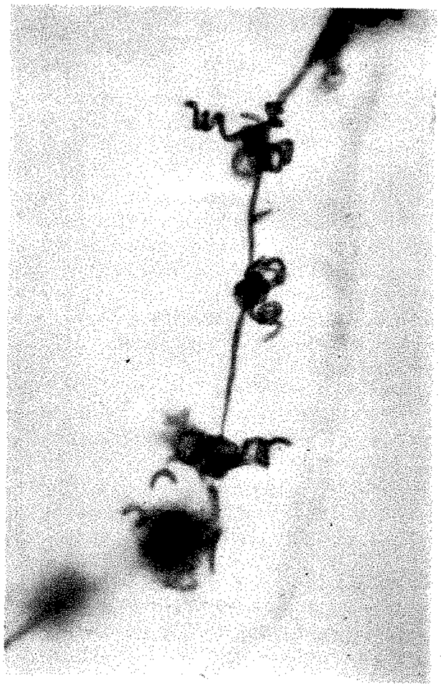

Fig. 1. Aerial mycelium of isolate *A*5279 (× *c*. 530)

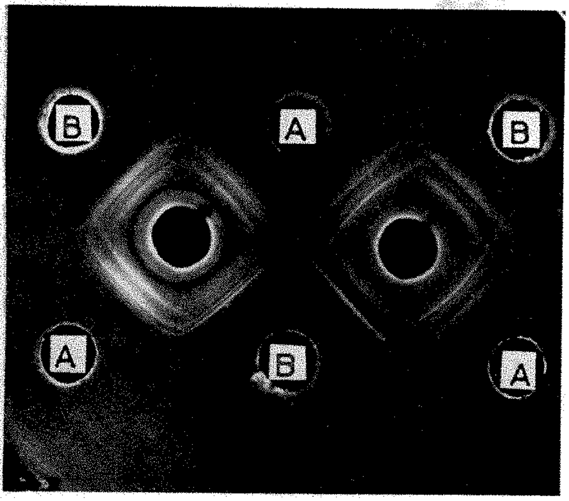

Fig. 2. Photograph of agar diffusion plate. Centre wells contain immune serum to isolate *A*5279, surrounding wells contain antigens (*A*), *A*5279; (*B*), *S. rimosus*

hyphæ. Because of the close similarity of these strains to *S. rimosus* and the common production of oxytetracycline it is suggested that they are variants of *S. rimosus* with coiled to spiral sporophores separated by long internodes and would be more satisfactorily included under the name *S. rimosus* forma *pseudoverticillatus*.

Further evidence of the relationship between *A*5279 and *S. rimosus* has been obtained serologically using the Ouchterlony gel diffusion method (Fig. 2). It appears that *A*5279 and *S. rimosus* have four and possibly five common antigens. *A*5279 has one strong antigen which cannot be detected in *S. rimosus* and conversely all the *S. rimosus* antigens are to be found in *A*5279. This would again suggest a very close relationship and at the same time a strain difference which is illustrated by the different aerial mycelium morphology.

GENETICS

Possible Genetic Evidence of Somatic Segregation in *Allium cepa* L.

Reduction in somatic nuclei has been noted in various plants and animals by a number of workers. This communication reports an instance in which both glossy and semi-glossy seed-stems were found on the same onion plant. Huskins[1] has reviewed many examples in the plant field, thus a full review will not be given here, but only a few more pertinent examples will be cited. Segregation and/or reduction in chromosome number was induced in cells of onion root tips which had been treated with 1–4 per cent sodium nucleate. Regular genetic segregation occurred with greater frequency than would be expected if the distribution of the chromosomes were a random process[2]. Onion bulbs stored at 5°–6° C. showed a reductional grouping[3].

During the growing season of 1954, 17 plants with both glossy and semi-glossy seed-stems were found in a population of about 500 of the Yellow Sweet Spanish onion inbred *B* 12132. The inbred *B* 12132 is not homozygous for the semi-glossy character. Jones, Clarke and Stevenson[4] reported that glossy foliage was recessive to non-glossy. Apparently, semi-glossy is dominant to glossy but recessive to non-glossy. Bulbs stored at the University of Idaho, Branch Experiment Station, Parma, Idaho, at temperatures of 5°–7° C. were set in the field in late March.

Two bulbs—one a *B*-line (fertile) bulb and the other an *A*-line (male-sterile) bulb—were selected for further study. The *B*-line bulb produced three seed-stems, one of which was semi-glossy and two were glossy; however, only a few seeds were obtained. No plants survived from seed produced on the umbel of the semi-glossy seed-stem. The foliage of the progeny of the two glossy seed-stems was glossy.

The *A*-line bulb produced two seed-stems, one of which was semi-glossy and the other glossy. The *A*-line bulb was crossed to a glossy plant. No seed was obtained from the glossy seed-stem. All the plants from the seed on the semi-glossy seed-stem, which had been crossed to glossy, were semi-glossy. The F_1 when crossed to glossy gave a segregation ratio of 1 : 1.

The F_1 hybrid of a cross between glossy and semi-glossy foliage is semi-glossy. The F_2 segregates in the ratio of 3 semi-glossy to 1 glossy. In this particular instance, both types appeared on the same plant. Progeny from the glossy seed-stem bred true for glossy. Similarly, progeny from the semi-glossy seed-stem bred true for the semi-glossy character. Only true-breeding individuals were obtained. A change occurred in the inheritance pattern of the glossy seed-stem character of the onion. The change could have been caused by the loss of a segment of chromatin carrying the dominant gene, though the high percentage of plants with both glossy and semi-glossy seed-stems makes this unlikely. The change could have been caused by a point mutation, but two simultaneous mutations would have to occur. Somatic reduction of chromosomes could be responsible for two true-breeding lines in an otherwise heterozygous individual. If the latter possibility is true, then the common bulb onion, *A. cepa*, offers an excellent opportunity for study of somatic reduction in plants.

A Human Double Cross-Over

An X-linked blood group system, Xg, was described this year jointly by investigators in the United States and at the Medical Research Council, Blood Group Research Unit, at the Lister Institute[1]. More recently it was shown, at the University of North Carolina[2], that while 'classical' hæmophilia (hæmophilia A) is closely linked to colour blindness, as was already known from the work of Haldane and others, hæmophilia B (ptc deficiency, Christmas disease) is very loosely linked to colour blindness, if linked at all. In English families the loci for Xg and for hæmophilia A have been found to be widely separated[3]. Though work in progress is showing no hint of linkage between *Xg* and colour blindness the two should, in theory, be within measurable distance of each other because colour blindness is close[4-6] to the locus for glucose-6-phosphate dehydrogenase deficiency (g-6-pd) and g-6-pd is within measurable distance[7] of *Xg*.

During an investigation of the Xg-hæmophilia B relationship we have tested a family which can be scored for *Xg*, hæmophilia B (*h.ptc*) and colour blindness (*cb*). This is the first human family in which three genes on one chromosome have been seen to segregate with crossing-over between each, and furthermore, it shows at least one double cross-over.

The pedigree chart (Fig. 1) is a modification and extension of that published elsewhere[2]. The mother, known to be heterozygous for hæmophilia B and protanopia, is also heterozygous for Xg, Xg^aXg, for she is Xg(a+) and has Xg(a−) children. Each of the five sons is unique; they demonstrate five of the eight single chromosome combinations possible from a triply heterozygous mother.

It is intriguing to speculate about the linear order in which the three loci are arrayed. Three orders (and their opposites) are possible: (I) *cb—Xg—h.ptc* ; (II) *cb—h.ptc—Xg* ; (III) *Xg—cb—h.ptc*. Order II, with *h.ptc* in the middle, appears to be excluded for the following reason: the present family[2] shows that *cb* and *h.ptc* cannot be close to each other, for at least two of the five brothers must be recombinants; work in progress is showing *Xg* and *h.ptc* to be widely separated, yet *Xg* and *cb* are likely, for reasons given here, to be within measurable distance of each other.

There is at present little to guide the choice between orders I and III. In Fig. 1 we have used I. The reader can verify that all three orders involve double cross-overs.

Whichever order is correct the three pairs of genes could be aligned in four different fashions in the two X-chromosomes of the mother. However, at least one double cross-over must be accepted, whatever the alignment. The family data[2] indicate that configuration A is more likely than configuration B, but it was not possible to distinguish between options 1 and 2 because the Xg groups of the maternal grandfather and grandmother are not known.

The occurrence of at least one double cross-over in this family combines with other linkage studies to show that these three genes are well separated; they may span as much as 100 map units of the X chromosome.

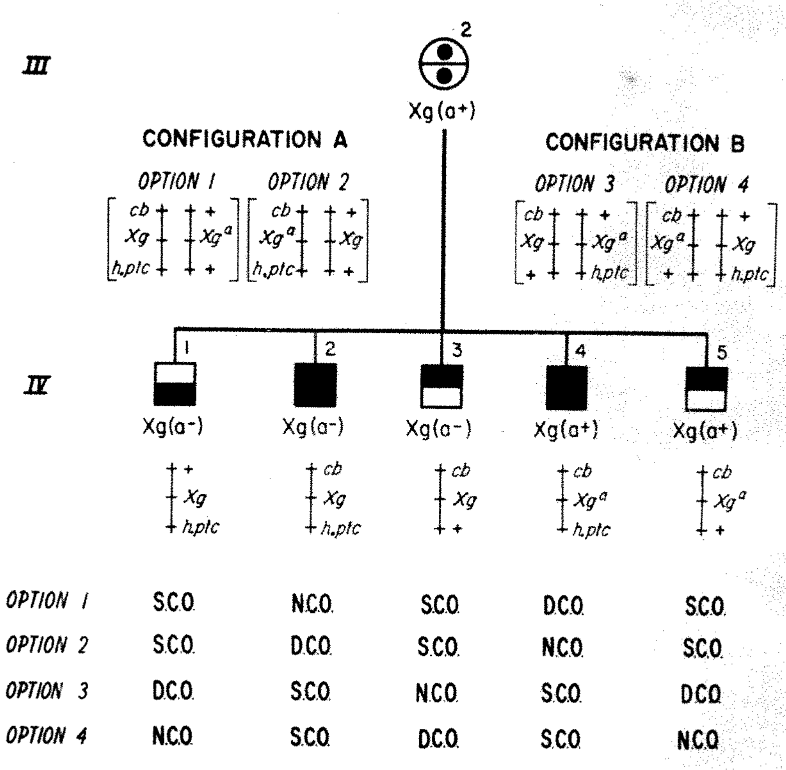

Fig. 1. Segregation in one family of three pairs of X-linked genes: those for colour blindness (protanopia), for hæmophilia B (ptc deficiency, Christmas disease) and for the Xg blood groups. Squares, males; solid upper half, colour blind; solid lower half, hæmophilia B; open, normal. Circle, female; dots represent a carrier of the colour blind and hæmophilia B genes. Genetic notation: +, normal gene; *cb*, colour blindness gene; *h.ptc*, hæmophilia B gene; Xg^a, the gene responsible for the antigen Xg^a and *Xg* represents its allele which causes no antigen yet identified. N.C.O., non-cross-over; S.C.O., single cross-over; D.C.O., double cross-over

VIROLOGY

Simultaneous Activation of Pentose Phosphate Shunt Enzymes in a Virus-infected Local Lesion Host Plant

In the course of work on the biochemical basis of plant virus localization it has been found that around the necrotic lesions of *Nicotiana glutinosa* leaves infected with tobacco mosaic virus (TMV) the dehydrogenases are highly activated as shown by the *in vivo* application of the triphenyl tetrazolium chloride (TTC) technique[1] Because of the possible implication of oxidative metabolism in resistance phenomena, the nature of the enzymes involved was examined Our attention was directed to the pentose phosphate cycle enzymes as alterations in their activities were recently reported to occur in host tissues infected by fungal pathogens[2,3] Isotope investigations also suggested an increased *in vivo* role of the pentose phosphate cycle in these hosts[4,5] Virus diseases have not been investigated from this point of view so far, although the host–virus systems offer distinct advantages, the direct contribution of the pathogen to the enzymatic changes occurring in the host was in this way excluded

In the present work *Nicotiana tabacum* var White Burley plants were inoculated mechanically with the *para* strain of TMV[6] The infection resulted in the development of necrotic local lesions surrounded by a yellow ring of living tissue Infiltration with 0 6 per cent TTC led to the rapid appearance of red colour around the lesions, indicating the area of enhanced dehydrogenase activity From the corresponding tissues of a number of infected leaves not infiltrated with TTC, disks were punched out with a miniature cork borer (2 5 mm *d*) The cell-free extract of 120 disks was used for the spectrophotometric assays An equal number of disks punched from the normal green areas of the same leaves served as controls

A representative experiment is shown in Fig 1 It may be seen that in the tissues surrounding the lesions the activity of glucose-6-phosphate dehydrogenase is increased by about 300 per cent over the control Similar or even higher activation of 6-phosphogluconate dehydrogenase was found in several consecutive experiments

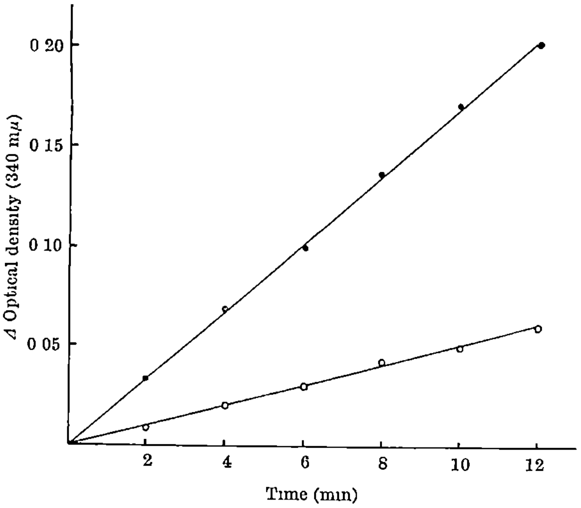

Fig 1 Activity of glucose-6-phosphate dehydrogenase in White Burley tobacco leaves infected with the *para* strain of TMV ●, Extract from tissues surrounding local lesions, ○, extract from normal green areas of the same leaf Composition of the system 2 5 μM glucose-6-phosphate, 0 25 μM triphosphopyridine nucleotide, 1 μM magnesium chloride Enzyme corresponding to 20 mg fresh weight Glycyl-glycine buffer *p*H 7 5 Final volume 1 5 ml Light path, 0 5 cm

From a biochemical point of view, it is quite remarkable that two members of a cycle are affected simultaneously in the same sense despite the fact that the two enzymes are distinct, soluble proteins The nature of increased activity (*de novo* protein synthesis, removal of inhibitors, activation) is under investigation

The role in host–virus interactions of the phenomenon described here is not fully understood, however, it might be postulated that the enhanced production of reduced triphosphopyridine nucleotide by the dehydrogenases involved plays a part in maintaining a high phenol/quinone ratio, thereby hindering the growth of the lesions[7]. Further investigations along these lines might contribute to the elucidation of the biochemical nature of localized acquired resistance of the tissues surrounding the virus-induced lesions[8,9]

Serological Relationship of Chrysanthemum Virus *B* to Carnation Latent Virus and Potato Viruses *M* and *S*

When leaf extracts from chrysanthemum plants infected with chrysanthemum virus *B* (CVB) were tested against antisera to 22 different elongated plant viruses, those prepared against carnation latent virus (CLV), potato virus *M* (PVM) and potato virus *S* (PVS) gave a positive serological reaction In reciprocal tests an antiserum prepared against CVB itself reacted positively with partially purified preparations of CLV, PVM and PVS

These results indicate that CVB should be included in the group of plant viruses hitherto represented by CLV, PVM and PVS, the serological relationships of which have already been established among previous authors[1–4]

In Table 1 the average homologous titres of the antisera to CLV, CVB, PVM and PVS respectively are summarized together with their titres against the heterologous viruses of the group

Table 1 Virus Preparation Tested

Antiserum to	CLV	CVB	PVM	PVS
CLV	8192	32	128	32
CVB	256	2048	32	64
PVM	16	16	2048	16
PVS	64	128	32	4096

The relatively large differences between homologous and heterologous titres suggest a major antigenic fraction specific for each virus together with minor fractions common to two or more viruses of the group.

On the morphological basis of 'normal length', estimated by electronmicroscopy, Brandes[5] has ranged chrysanthemum virus *B* in a group of viruses which among others includes CLV, PVM and PVS.

PSYCHOLOGY

Theoretical and Empirical Confusion Functions

CROSSMAN[1] produced an empirical 'confusion function' with a value for a pair of stimuli proportional to the time taken to discriminate between them.

Hammerton[2], from a mathematical model of perception, has derived theoretical confusion values in good agreement with Crossman's for, roughly, $3 > x_2/x_1 > \frac{1}{3}$, where x_1 and x_2 are the two stimulus values. Welford[3] has pointed out that $K \frac{(x_2 + x_1)}{x_2 - x_1}$ differs by very little from Crossman's confusion function $\frac{1}{\log_2 x_2 - \log_2 x_1}$ (K a constant) except when x_1 and x_2 are very different, and then Welford's formula gives good agreement with Hammerton's confusion values. Unfortunately, this agreement is coincidental and results from an unjustified assumption made by Hammerton.

The model assumes "that (*a*) an act of perception is based on a population of values—perhaps, for example, of neurone firing-rates—normally distributed about the correct magnitude, that (*b*) the standard deviation of such a population bears a constant ratio (taken as unity for simplicity of computation) to the value of the mean", that is, if we take $\frac{\text{standard deviation}}{\text{mean}} = k$, then it is assumed that $k = 1$. This is the unjustified assumption.

The theoretical confusion function is $C \propto \frac{1}{1 - A}$ where A is the area of the overlap of the distributions of x_1 and x_2, and

$$A = \frac{1}{\sqrt{2\pi}\, k} \left\{ \frac{1}{x_1} \int_{-\infty}^{p} \exp\left[- \frac{(x - x_1)^2}{2k^2\, x_1^2} \right] dx \right.$$

$$\left. + \frac{1}{x_2} \int_{p}^{q} \exp\left[- \frac{(x - x_2)^2}{2k^2\, x_2^2} \right] dx + \frac{1}{x_1} \int_{q}^{\infty} \exp\left[- \frac{(x - x_1)^2}{2k^2\, x_1^2} \right] dx \right\} \quad (1)$$

and p and q are the roots of

$$\frac{(x - x_1)^2}{2k^2\, x_1^2} - \frac{(x - x_2)^2}{2k^2\, x_1^2} - \ln \frac{x_2}{x_1} = 0 \quad (2)$$

Now it is seen that if the population of values is in fact that of neurone firing-rates, then the substitution $k = 1$ is unrealistic or unjustified, since negative firing-rates are impossible and consequently the distribution of values must be markedly non-normal, so that putting $k = 1$ in equations (1) and (2) would give incorrect values for A.

Further, we should expect that C would bear some relation to errors. In fact, if $p(x_1) = p(x_2) = 0.5$, and if $p(e)$ is the probability of an error, then we must have $p(e) \geq A/2$. In that case, if $k = 1$ and $x_2/x_1 = 2$, $p(e) > 0.3$, which is far too high a value, even for Crossman's experiments, in which errors were appreciably higher than the minimum possible.

Finally, $p(e)$ decreases with increase in observation time (up to about $\frac{1}{2}$ sec.[4]) and so, conceivably, k changes during an observation.

Thus it is difficult to justify the assumption that k has any particular value, and especially difficult to justify the assumption that it has a value as large as 1, and yet p, q, A, and consequently C, are all sensitive to changes in k.

Table 1. VALUES OF THEORETICAL AND EMPIRICAL CONFUSION FUNCTIONS

	x_1/x_2							
Hughes	0	0.5	0.67	0.75	0.80	0.83	0.86	0.88
Crossman	0.00	1.00	1.71	2.41	3.13	3.82	4.51	5.18
Welford	0.33	1.00	1.67	2.33	3.00	3.67	4.33	5.00
Hammerton								
$k = 1$	0.34	1.00	1.64	2.28	2.92	3.57	4.35	4.86
$k = 1/14$	1.00	1.00	1.00	1.05	1.11	1.25	1.39	1.54

Values of the theoretical C are tabulated for $k = 1$ (from Hammerton), and $k = 1/14$, together with the corresponding values of the expressions put forward by Crossman and Welford. The values for $k = 1$ were all multiplied by Hammerton by a constant factor to give $C = 1$ for $x_1/x_2 = 0.5$. Similarly, a constant factor $K = \frac{1}{3}$, is required in Welford's formula to give $C = 1$ for $x_1/x_2 = 0.5$, and since in both formulæ the uncorrected value of $C \rightarrow 1$ as $x_1/x_2 \rightarrow 0$ or ∞, the agreement of corrected values of C for extreme values of x_1/x_2 clearly depends on the value of k chosen in Hammerton's model. For $k = 1/14$ $A < 0.000005$ and $C = 1$ very nearly when $x_1/x_2 = 0.5$, so that no correction factor is needed. It is seen that values of C for $k = 1/14$ are markedly different from those of the other formulæ apart from the arranged agreement at $x_1/x_2 = 0.5$, and yet this value of k, far from being unrealistically small, may still be over-large, since it corresponds to $p(e) = 0.02$, 0.08 and 0.17 for $x_1/x_2 = 0.75$, 0.8 and 0.875. It would, of course, be possible to arrange agreement among the formulæ at some value of x_1/x_2 other than 0.5, but this would produce no general improvement, nor would it remove the apparent paradox, which is in fact the result of adjusting Hammerton's formula: that the smaller the value of k, that is, the greater the separation of x_1 and x_2 in standard deviations, the larger the adjusted value of C for $x_1/x_2 = 0$.

Sunday, September 2

At 11 a m —Service in Manchester Cathedral Preacher The Lord Bishop of Manchester, the Right Reverend Dr W D L Greer, D D

Monday, September 3

At 10 a m —Prof F W Shotton, F R S "The Physical Background of Britain in the Pleistocene Period" (Presidential Address, Section C)

At 10 a m —Mr L P Kirwan "Nubia—an African Frontier Region" (Presidential Address Section E)

At 10 a m —Mr W B Reddaway "The Economics of Underdeveloped Countries" (Presidential Address, Section F)

At 10 a m —Prof Bruce Pattison "English as an International Language" (Presidential Address, Section X)

At 8 p m —Prof Sir Alister Hardy, F R S "Man and the Beneficent Sea" (Evening Discourse)

Tuesday, September 4

At 10 a m —Dr. M R House "Bursts in Evolution" (Darwin Lecture)

Wednesday, September 5

At 10 a m —Mr R A French ' The Making of the Russian Landscape" (Lister Lecture)

Monday, September 3—Friday, September 7

International Conference on Water Pollution Research (at Church House, Westminster, London, S W 1)

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned

Lecturer in the Pharmacology Department—The Dean, Guy's Hospital Medical School, London, S E ,1 (August 31)

Leverhulme Student (with a postgraduate diploma in chemical engineering or equivalent qualifications) in Chemical Engineering—The Registrar, King's College (University of London), Strand, London, W C 2 (August 31)

Scientific Assistant in the Pharmacy Department, for the maintenance of physical instruments including spectrophotometers and radiochemistry equipment, and duties will also include certain routine measurement and demonstrations—Chelsea College of Science and Technology, Manresa Road, London, S W 3 (August 31)

Assistant Lecturers (with a good honours degree and preferably with industrial, research or teaching experience) in Physics and Applied Physics—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff (September 1)

Assistant Lecturer in Agricultural Economics—The Registrar, The University, Manchester 13 (September 8)

Assistant Lecturer or Lecturer (with special interests in inorganic chemistry) in Chemistry—The Registrar, The University, Sheffield (September 8)

Assistant Lecturer (with a good honours degree in physiology) in Physiology—The Registrar, The University, Manchester 13 (September 8)

Assistant Lecturer (with a good honours degree in physiology, biochemistry or chemistry with subsidiary physiology) in Chemical Physiology—The Registrar, The University, Manchester 13 (September 8)

Research Assistant (with a good honours degree) in the Department of Agriculture and Horticulture, Research Station, Long Ashton, for work in plant biochemistry, with special reference to photosynthesis—The Secretary, The University, Bristol (September 8)

Lecturers (preferably with a special interest and research experience in one or more of the following plant physiology, mycology, anatomy, or flowering plant systematics) in the Department of Botany, University of Ghana—The Registrar, University of Ghana, P O Box 25, Legon, Accra, or the Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W C 1 (September 10)

Research Assistants (2) (graduates in geology) in the Department of Geology, to undertake research on Upper Palæozoic conodont faunas—The Registrar, University College of Swansea, Singleton Park, Swansea (September 10)

Lecturer in Physics—The Registrar and Clerk to the Governors, College of Technology, Park Road, Portsmouth (September 14)

Research Student in the Department of Psychology—The Registrar, The University, Hull (September 14)

Reactor Engineer (with a university degree in engineering or an equivalent qualification, several years industrial experience, and preferably some experience in plant operation) in connexion with the projected nuclear reactor to be operated jointly by the University of Liverpool and the University of Manchester—The Bursar, The University, Manchester 13 (September 15)

Chair of Botany in the University of Ghana—The Registrar, University of Ghana, P O Box 25, Legon, Accra, or The Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W C 1 (September 17)

Assistant Experimental Officer (graduate) in the Bee Department, for work on field behaviour of bees, including pollination—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 17)

Coal Petrologist (with a university degree or a Technical College Diploma or equivalent with geology as a major subject) in the Division of Coal Research, Commonwealth Scientific and Industrial Research Organization, North Ryde, New South Wales, Australia, to carry out investigations on the microscopy of Australian coals and cokes—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W C 2, quoting Appointment No 480/415 (September 22)

Chair of Zoology—The Secretary, The University, Edinburgh—(September 30)

Lecturer (honours graduate in mathematics or mathematical physics and an interest and experience in the application of mathematics to engineering problems, and preferably experience in programming high-speed digital computers for scientific and engineering problems) in the Department of Mathematics—The Registrar, College of Aeronautics, Cranfield, Bletchley, Bucks (September 30)

Lecturer or Senior Lecturer in Pure Mathematics at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1 (Australia and London, October 1)

Senior Lecturer or Lecturer (preferably with an interest in chemical spectroscopy) in Theoretical Chemistry in the School of General Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1 (Australia and London, October 1)

Research Officer or Research Cadet (with an honours degree in agriculture, science or veterinary science), for research on animal nutrition—The Director, An Foras Taluntais (The Agricultural Institute), 33 Merrion Road, Dublin 4, Republic of Ireland (October 5)

Chair of Pure Mathematics in the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1, or The Registrar, University of Canterbury (New Zealand and London, October 15)

Chemist or Biochemist (honours graduate), for research on enzymes of liver and other tissues—Dr B Levin, Queen Elizabeth Hospital for Children, Hackney Road, London, E 2

Chief Technician (with experience of general laboratory techniques and equipment, and preferably a knowledge of microanalytical work and animal experimentation) in the Pharmacology Unit—The Secretary, Institute of Animal Physiology, Agricultural Research Council, Babraham, Cambridge

Research Assistant (with a B Sc special chemistry degree of the University of London) in the Chemistry Department, for a research problem in physical-organic chemistry involving a study of the kinetics and mechanism of oxidation processes in solution—The Registrar, Brighton College of Technology, Richmond Terrace, Brighton, Sussex

Research Assistant (with a degree, diploma in technology, or equivalent qualification) in the Department of Applied Physics, for research on subjective brightness—Head of the Applied Physics Department, Northampton College of Advanced Technology, St John Street, London, E C 1

RESEARCH ASSOCIATE (interested in ultra-structural studies related to degenerative changes in human nerve)—Dr J B Finean, Department of Medical Biochemistry and Pharmacology, The Medical School, The University, Birmingham 15

RESEARCH FELLOW (with a Ph D or equivalent and some experience in cryogenics) IN LOW TEMPERATURE PHYSICS, to study nuclear and electronic interactions in ferromagnetic and anti-ferromagnetic metals at very low temperatures—The Secretary and Registrar, The University, Southampton)

SCIENCE GRADUATE (preferably with honours, and experience in the fields of immunochemistry, immune serum production or protein fractionation) with the Edinburgh and South-East Scotland Blood Transfusion Service and Blood Products Unit—The Regional Director, Blood Transfusion Service, Royal Infirmary, Edinburgh 3

TECHNICIAN IN THE INORGANIC CHEMISTRY LABORATORY, to assist in servicing and maintenance of instruments and apparatus—F M Brewer, Inorganic Chemistry Laboratory, South Parks Road, Oxford

PLANNING SCIENTIFIC INVESTMENT

IN an admirably balanced presidential address, Sir John Cockcroft used the unique opportunity afforded by the British Association for the Advancement of Science to remind Britain of the vital importance of an adequate and appropriate investment in science (see also p 875 of this issue) His title recalls a recent study by the National Science Foundation, *Investing in Scientific Progress,* which attempted to estimate the investment which the United States should make in science and in engineering education and in fundamental research in its universities (see *Nature,* 194, 320, 1962) It also brings to mind the report of the committee under the chairmanship of Sir Charles Morris which, under the title *Investment for National Survival,* put the expenditure needed for future educational development as likely to approach £1,500 million by 1970 (see *Nature,* 194, 801, 1962) Sir John referred, indeed, to educational development, more especially to the need for more scientists and technologists, and there was no suggestion in his address that supply is anywhere near approaching demand He owed nothing to either of these two studies, however, and his main theme was the need for an adequate and balanced research effort, in which full account was taken of the possibilities for co-operation, both at the national and the international level

Appropriately enough, Sir John began his survey with a glance at the work on radioactivity which was proceeding in Rutherford's laboratory when the Association last met in Manchester It would be difficult to think of any work that seemed less likely to find practical application, yet within five years Rutherford was fairly certain that nitrogen atoms were disintegrated by the impact of his alpha-particles, within a quarter of a century his experiments led to the first controlled release of nuclear energy in Fermi's atomic pile, and within forty years of the Manchester meeting half a century of work by physicists and engineers of many nations had led to the first large-scale nuclear power station in Britain Nuclear power provides, in fact, an outstanding example of the importance of fundamental research—of ensuring that the universities, and, it might be added now, the colleges of technology, have at their disposal adequate resources for research, of choosing men of first-class ability and giving them their head

Sir John was not tempted to dwell unreasonably on nuclear physics as it still remains in an intensely creative phase He noted the immensely powerful tools which have been placed at man's disposal in the synchrocyclotron, the proton-synchroton or Cosmotron and the Berkeley Bevatron, which have permitted the creation of anti-matter and the study of the physics of anti-matter He stayed no more than to point out the challenge presented by the recent discovery of still more ephemeral particles at Berkeley and the possibilities offered of enriching man's understanding of the physical universe as indicating that the study of elementary particles was likely to be in the forefront of physics for several decades and to continue to attract many of the world's best scientists

This, Sir John continued, was sufficient reason for maintaining the present heavy investment in this branch of science, but while this work with very-high-energy particles proceeded, another group of nuclear physicists, working with less-energetic particles of very precisely defined energies, was exploring the detailed structure of the nucleus and its vibrations and oscillations, as well as the nuclear processes which lead to the evolution of the elements in the stars In consequence, it is now known how this evolution starts, and Sir John also referred to the way in which radioastronomers and optical astronomers had extended estimates of the age of our Galaxy and were striking farther and farther out into the boundaries of the universe Moreover, optical astronomers were moving out into space to avoid the interference to their measurements by the absorption of ultra-violet and X-rays in the atmosphere, so that in consequence astronomy had combined with space science to rival nuclear physics in the size of its budget

Sir John said nothing to indicate that he thought a budget of £5 million a year unreasonable for Britain in this field alone, though he clearly thought that economic necessity as well as scientific interest involved collaboration, first with the United States and in future with Western Europe Later in his address he expressed the emphatic opinion that international collaboration in fundamental research was of growing importance—the only way in which sufficient resources could be made available in nuclear physics and space research, for example What he described as space travel was another matter, and he expressed the opinion that the ventures on which the United States and Russia were each spending something of the order of 2,000–3,000 million dollars a year were being undertaken mainly for prestige purposes Frankly, he thought the priorities had gone wrong, and while it was necessary to increase investments in science as rapidly as human and financial resources could permit, it was not for such purposes as these

Sir John said no more on the magnitude of Britain's investment in science than that if Britain wished to maintain her position in the highly technological world of the future it would be necessary to double the 0 2 per cent of the gross national product devoted to basic research during the next decade, and also to devote a much greater proportion of the effort in applied research to furthering the development of new products and new industries The value of his address lies rather in the way it displays the conspectus of the research effort which is demanded and what is involved if Britain's available resources are to be deployed to the best purpose For example, he pointed out that in Britain and in the world generally the physics of the solid state attracts as many research workers as nuclear physics and that their achievements have probably been of more immediate practical use Moreover, like the nuclear physicists, they have been greatly helped by the more powerful and discriminating instruments which advancing technology has made available Again, this is one of the basic reasons for the mounting costs of research equipment which is compelling collaboration up to the international level The development of the transistor industry provides a spectacular example of the interaction of science and technology, and has had far-reaching effects on other fields such as electronic equipment and the computer, and, through these, on the development of sciences such as molecular biology, high-energy nuclear physics, the study of stellar evolution and plasma physics, quite apart from space research

All this was scarcely predictable little more than a decade ago, and the way in which the different fields of science and technology are to-day interdependent could scarcely be better illustrated No more effective answer could be given to those who contend that Britain can afford to leave entirely alone any specific field of basic research where the effort is justifiable on scientific grounds and not on those of prestige The study of semi-conductors, which has led to the development of transistors, only began as an academic subject some thirty years ago, and it has also led to rectifiers of increasing importance in power generation, to devices for producing refrigeration, to solar batteries and many other products

Sir John pointed out that the sciences dealing with the Earth and its environment were in an equally lively state, and he referred incidentally to the belief of oceanographers that more extensive studies of the nutrient content of the deep ocean and methods of increasing the turnover could lead to greatly increased production of fish protein which, at present, provides only about 1 per cent of the Earth's food Here we infringe on fisheries research, which is probably one of the most important ways in which Britain could continue the overseas research effort to which Sir John referred in the latter passages of his address, particularly if the needs of the increasing population for greater food supplies are to be met This may be the more important in view of the disinclination of the emergent territories to devote their own resources to such research

The development of the biological sciences likewise has been greatly helped by the new techniques and instruments which technological developments in other fields have placed at their disposal Furthermore, a remarkable example of inter-disciplinary collaboration has led to a discovery which Prof Medawar has said puts into man's power, in principle in the very remote future, the possibility of exercising a primary and direct control over genetic make-up even to secure a direct and fundamental cure of inborn disorder Biochemists also seem to be making progress in the control of fertility, and the application of technology to increase agricultural production in under-developed countries may be supplemented by turning fishing from a hunting to a farming operation and by new approaches to providing protein for human food.

Sir John concluded his review of some of the more outstanding recent developments in these and other fields, including that of energy, by asking the question whether the organization of applied research could be improved and whether Government assistance could be more effective He thought that Britain might have something to learn from some American organizations, but that there was a critical size for an industrial research establishment if creative work was to flourish Obviously, to-day, there is a limiting size below which an establishment will be unable to provide the highly expensive equipment which is essential in many fields of research, but otherwise it is arguable whether organization rather than size is not the critical factor When this question was discussed in a symposium on the direction of research establishments at the National Physical Laboratory in September 1956, there was no suggestion that size was of any importance The provision of conditions favourable to creative work is what matters, and this can be done in the large or the small establishment Indeed, the large establishment may be the better able to provide stimulating inter-disciplinary contacts

Everything in fact depends on the outlook and understanding of management and, as Sir John pointed out, we must get a much higher proportion of scientists and engineers into managerial positions So far from there being any likelihood of an excess of scientists and technologists in the next decade, he thought that the major obstacle to university expansion would be a shortage of highly qualified mathematicians, scientists and technologists He remarked that the best way to reduce the present loss of scientists to the United States was to improve the research facilities at home, and that Britain needs a steadily continuing increase in research grants to the universities to match the growth of the research schools and the increasing complexity of research tools This must include adequate funds for the social sciences also, which have hitherto been allowed to depend too much on funds from foundations in the United States

In thus displaying the opportunities for investment in science which confront us to-day, Sir John was content to indicate the magnitude of those opportunities, the way in which the different fields are interrelated and the extent to which co-operation is now indispensable, even to nations with resources and traditions such as Britain still possesses He made no attempt to suggest how Britain's effort should be deployed nor did he enter on any discussion of the adequacy of the existing organization for research and development These all involve political issues, as does the question of Britain's future policy in overseas research, for which he saw a clear and urgent need, and in fact suggested that if the political difficulties in achieving disarmament could be overcome, enormous resources would be released for diversion to the urgent needs of the under-developed countries

Fundamentally, Sir John's address was a challenge to his audience, and to the many thousands whom his words will have reached by radio or in print, to see that the question of adequate and effective investment in science is made a real political issue and one that is honestly faced by all political parties Understandably and correctly, the Government in power realizes that there are definite limits to the extent of Britain's investment in science set by finance, material resources and manpower, but neither major political party has yet been honest enough to put to the country what would really be involved by an adequate investment in science and technology Neither has had the courage to admit that such an investment may be incompatible with unlimited expenditure in non-essentials, even on things that to-day in Britain, if nowhere else, are taken into account in calculating the cost-of-living index

Political courage and honesty are prerequisites in determining the level of investment in science, and without them the financial resources are unlikely to be forthcoming Whether or not Britain's existing organization for determining the allocation of resources, which is at present under scrutiny, is the most appropriate and effective, something more is needed Ultimately the allocation of resources, like the wise selection of research projects, the determination of priorities and the choice of policies, is a matter of sound judgment What matters most in these questions of science and Government is that the structure for presenting scientific advice should both ensure that that advice is presented effectively at policy-level to those capable of appreciating its significance, and that in the formulation of that advice there is full opportunity of authoritative discussion and criticism Above all, it should ensure that the advice presented does not reflect the prejudices, obsessions or limitations of a single mind It is as a contribution to the task of educating public opinion as to what is really implied by adequate investment in science that Sir John's presidential address to the British Association was most welcome Scientists and technologists will best show their appreciation by responding to his challenge and making what contribution they can, not only in solving the technical problems of controlled and complete disarmament but also in continuing the task of educating public opinion and securing the appropriate action required to increase the investment in science in the widest sense

DEATH OF NAPOLEON

Who Killed Napoleon?

By Dr Sten Forshufvud Translated from the Swedish by Alan Houghton Brodrick Pp 256+8 plates (London Hutchinson and Co, Publishers, Ltd, 1962) 25*s* net

THIS book is unlikely to gain general popularity, if only for the lengthy descriptions of the more unpleasant features of Napoleon's illnesses in St Helena Its one merit lies in the convenient presentation of the lives and characters of those persons in attendance on the Emperor during his last exile The merit that the author would ascribe to it lies in his contention that Napoleon was systematically poisoned over many years by the administration of arsenic and, finally, in the classic style of the French arsenic poisoners of the seventeenth century, that he was given antimony so as to cause evacuation of the previous doses of arsenic The *coup de grâce* is stated to be a dose of 10 grains of calomel ordered by four doctors, three of whom were British (the fourth, Antommarchi, disapproving) This calomel was changed into hydrocyanic acid and corrosive sublimate through interaction with a fruit drink containing bitter almonds!

The author has a doctor's degree but practises as a dental surgeon, from his presentation of clinical material it is difficult to believe he has any proper knowledge of medicine and one presumes his degree is in dental surgery In his wearisome discussions on the effect of the 'climate' of St Helena on Napoleon's health, he speaks entirely as a layman and seems to know nothing of the bacterial infections which exist in such places

Although the British Government dealt harshly with anyone who claimed that Napoleon's health was adversely affected by his sojourn in St Helena, it is very probable, and certainly fully acceptable, that he did indeed suffer during his five years these recurrent attacks of an infection that was associated with features of hepatitis This, indeed, is supported by the small portions of intestine that were presented by Barry O'Meara to Sir Astley Cooper and were found among Cooper's specimens after his death, and were labelled as Napoleon's It is probable that O'Meara secured them from Antommarchi, who visited him in London These fragments were from the lower part of the small gut and showed swollen and inflamed Peyer's patches such as would be found in a chronic bacterial infection that he could have acquired on the island The specimens were unfortunately lost when the Royal College of Surgeons was bombed in 1941

Whether or not the author is right in claiming that arsenic was administered to Napoleon there can be no doubt that post-mortem revealed a large cancer infiltrating the greater part of the stomach and with a perforation in one place sealed by an adherence to the left lobe of the liver Napoleon himself, during his last days, was convinced that he was suffering from a cancer of the stomach, a disease that caused his father's death, and he made a specific request that this lesion should be sought for so that his son could be warned about the danger of himself developing such a cancer

The presentation of the evidence for chronic arsenical poisoning is unsatisfactory, irritating and tortuous For most of the book the impression is gained that it was the "wicked British" who were responsible, but finally it is implied, although not specifically stated, that the poisoner was the Comte de Montholon (whose wife, incidentally, was Napoleon's mistress in St. Helena). The Count, in true thriller fashion, persuades Napoleon to change his will in his favour and when this is done recommences his final administration of poison!

It is implied, but not definitely stated, that he administered poison at the instigation of Talleyrand, and the author even claims that the administration must have been begun at Elba, and that certain of the indispositions Napoleon exhibited at the Battle of Waterloo "fit in very well with the general picture of arsenical poisoning"! It is also claimed that even earlier in his reign Napoleon was being drugged, at the instigation of the Great Powers fighting against him.

Napoleon is obviously the author's hero, but even this should not allow him to make errors in the assessment of history; he states that after his escape from Elba the whole of France welcomed him with joy. The truth is that the great mass of the French people were heartily sick of his antics, which had brought so many years of war and sorrow, and had resulted in almost every family grieving a father or sons. The only real support Napoleon met with on his last adventure was from the scores of thousands of his veterans who had been demobilized after peace was signed and, having known nothing but war because of his campaigns, were largely unsuited to return to civilian life and were, at that moment, glad of a chance to return to the life they knew. They were soon disillusioned. The rest of the nation had already been disillusioned. RUSSELL BROCK

LINEAR SPACES

Linear Algebra and Geometry

By Prof. Nicolaas H. Kuiper. Translated from the Dutch by A. van der Sluis. Pp. viii + 284. (Amsterdam: North-Holland Publishing Company, 1962.) 48s.

An Introduction to the Theory of Linear Spaces

By Prof. Georgi E. Shilov. Translated from the Russian by Richard A. Silverman. Pp. ix + 310. (London: Prentice-Hall International, 1961.) 50s.

Proceedings of the International Symposium on Linear Spaces

Held at the Hebrew University of Jerusalem, July 5–12, 1960. (A publication of the Israel Academy of Sciences and Humanities.) Pp. xi + 452. (Jerusalem: Jerusalem Academic Press; London and New York: Pergamon Press, 1961.) 100s.; 14 dollars.

LINEAR algebra is occupying an increasingly prominent place in the undergraduate mathematics curriculum. In the first place it is the basic mathematical tool in the study of the analytic geometry of n dimensions and in affine and projective geometry. Secondly, the notions of vector space and linear transformation are central to the study of systems of linear equations (and linear differential equations). Thirdly, these notions form a necessary and fairly elementary introduction to those concepts proper to group theory, to topology and to functional analysis, with which the student will have to familiarize himself later in his course. Fourthly, there is a growing realization of the importance and variety of the applications of linear algebra outside the domain of pure mathematics, for example, in statistics, linear programming, operational research. Fifthly, functional analysis and topological algebra constitute a very active area of present-day mathematical research and it is essential for any student aspiring to work in this field to familiarize himself thoroughly with the theory of finite-dimensional spaces. (Actually, the algebraic topologist also needs much of this basic theory; I myself, as an interested party, regretted the absence of a treatment of tensor products and exterior powers from the two text-books under review.)

The book by Kuiper is an excellent undergraduate text-book in which (as one would expect of the author) the geometric motivation is strongly, but not obtrusively, emphasized. Thus while the abstract concepts of vector space and mapping are given due prominence and the treatment is very largely co-ordinate-free, there are chapters devoted to Euclidean motions, to projective geometry and to non-Euclidean planes. Two further features of the book deserve mention. First, there is an interesting chapter on the applications in statistics, and, secondly, each chapter (except for the first two, which are brief) carries a number of stimulating and appropriate exercises. By way of mild criticism, however, it must be admitted that the book has clearly not been translated into English by an Englishman!

The book by Shilov is much less overtly motivated by geometric considerations. Whereas Kuiper is a geometer, Shilov is a functional analyst, and it is a measure of the ubiquitousness of linear algebra in mathematics that the actual contents of the two works overlap so substantially. In fact, it is Shilov's avowed object to introduce the reader to functional analysis. Not only is this intention made evident to some extent by the choice of material and style of presentation of the earlier chapters, but also the book closes with a long, and exceedingly valuable, chapter on infinite-dimensional Euclidean spaces, which constitutes one of the most accessible introductions to the basic concepts of functional analysis. The notions of completion, of orthogonal expansions, of bounded and completely continuous operators are discussed and there is a treatment of the eigenvector problem for a Fredholm operator and of the immediately relevant parts of the theory of integral equations. The book is well provided with examples, exercises and bibliography and its appearance bodes well for the series of translations of Russian texts of which it is the first. It was not to my taste that the book opened with a substantial chapter discussing determinants with Victorian formality (in the book by Kuiper, determinants appear on p. 91 as functions of endomorphisms of finite-dimensional vector spaces), and throughout the early chapters the treatment is perhaps excessively 'co-ordinatized'. But tastes vary, and the later chapters should suit most palates.

The third work under review contains the 32 papers read at the International Symposium on Linear Spaces held in Jerusalem during July 1960. The topics discussed range widely over the field of functional analysis and bear eloquent testimony to the vitality of this mathematical topic to-day. The Israel Academy of Sciences and Humanities is to be congratulated on the speedy publication of this record of an important conference.

P. J. HILTON

QUALITY AND QUANTITY IN SPACE AGE LITERATURE

Rocket Engines

By S L Bragg Pp 158+6 plates (London George Newnes and Co , Ltd , 1962) 35*s* net

Ballistic Missile and Space Vehicle Systems

Edited by Prof Howard S Seifert and Kenneth Brown (Engineering and Physical Science Extension Series, University of California, Los Angeles) Pp xii+526 (New York and London John Wiley and Sons, Inc , 1961) 96*s*

OF the many things with which we have been inflicted since the U S S R made the first moves into the 'Space Age' in October 1957, one is a proliferation of space literature and most of it is mediocre Perhaps editors and authors, inspired by the vastness of space, are making desperate efforts to fill the void with words Fortunately, we occasionally find an author who imposes strict limitations on himself and gives himself a precise objective It would seem that Bragg is such an author

With only a few innocent digressions from his objective, Bragg presents the important processes within a rocket engine in a logical and concise manner The overall impression is that one is following the thoughts of a man, sufficiently alert to discard trivialities, who is ascertaining what is of basic importance The result is a pleasant and readable book which, with a few words of caution, can be firmly recommended to students and anyone interested in rockets Some of the lapses from strict accuracy will be discerned immediately by the knowledgeable reader and later by those who are inspired to delve more deeply into rocket technology, but I myself would like to comment on statements made in sections 4 7 and 5 5 In the former section the relationship between propellent density and specific impulse is a sufficiently accurate approximation for the example quoted, but this example is scarcely typical of guided missiles The spectrum of missile designs is so wide that a single typical example cannot be quoted and the relationship between propellent density and specific impulse is more complicated than the author implies The statement, on p 91 in the latter section, to the effect that the drop in pressure generated in a combustion chamber by heat addition is not really a loss is both puzzling and incorrect When heat is added to a gas flowing in a duct, it suffers a fundamental loss in total pressure which cannot be recovered by subsequent cooling The extent of this fundamental loss is dependent on the degree of acceleration permitted, which in turn is dependent on the geometry of the duct, as Fig 5 4 indicates

In marked contrast to Bragg, Seifert and Brown have endeavoured to cover the whole gamut of disciplines and technologies necessary to design a launching vehicle and inject a satellite into orbit If they had succeeded in this task a really remarkable book would have been created, but it would have been of stupendous size As it is the book is too large when measured by the authority which it wields The first chapter, "Systems Engineering", carries tautology to extreme limits Its fourteen pages may be summarized as "Authority is vested in the systems engineer to ensure concentration, coordination and collaboration" If the two editors had assumed this authority something much better would surely have emerged What in fact has emerged is a series of articles each of a superficial character, and there is little evidence that the authors have perused their own efforts and still less that they have collaborated between themselves I am unable to visualize the reader who will derive much satisfaction from *Ballistic Missile and Space Vehicle Systems* It is certainly not the specialist in propulsion nor structures nor guidance and control Who is left but some enigma ! He may call himself a "Systems Engineer", but he is more likely to be a "Jack of all Trades"

Our language is flexible enough to meet the requirements of modern technology yet we abuse it in an appalling manner Bragg departs from his grandfather's precepts and meekly accepts "propellant' , but worse still, Seifert and Brown have accepted such abominations as "outage" and "fabricability" In both books the word "parameter" is frequently used, but never with its correct meaning Few of us who claim to have any scientific training, are endowed with much literary sense If we humbly acknowledge this we are likely to be more careful and less likely to make mistakes J E P DUNNING

REACTOR PHYSICS PRINCIPLES SIMPLY EXPLAINED

Textbook of Reactor Physics

An Introduction By J F Hill Pp 227 (London George Allen and Unwin, Ltd , 1961) 36*s* net

THIS book is a useful addition to the already numerous texts on reactor physics, and will provide easy reading to the many non-specialists who, although working in atomic energy, are not involved in detailed reactor physics calculations It also provides a stepping-stone between existing elementary and advanced works for those wishing to specialize in the subject In the writing of this book the author has drawn on the valuable experience he gained in teaching reactor physics to engineers and scientists while principal of the Harwell Reactor School He has therefore given clear physical pictures, without using involved mathematics, of the complex processes taking place in a nuclear reactor and anticipated the difficulties which come to the mind of the engineers and scientists who have little or no physics background

The book starts with an excellent summary on basic atomic and nuclear physics followed by a discussion on chain reactions and physics problems of reactor design A section on binding energy in this chapter, relating to the mass number-binding energy curve, is slightly misleading These topics are followed by a chapter on neutron behaviour in moderators, including an appendix clearly explaining the laboratory and centre of mass systems, neutron scattering and energy losses in collisions

Chapter 5 describes reactor parameters and discusses the critical size of a homogeneous reactor, starting with the 4 factor formula and including many useful graphs showing how these main parameters are affected, for example, by the ratio of the number of moderator to uranium atoms This chapter, of necessity, includes sections on the diffusion and slowing down lengths of neutrons, and it would be most useful if in future editions the author could add small appendixes on these topics

Chapter 6 shows the effect on the reactor parameters of changing from a homogeneous to a heterogeneous system It also gives numerical examples and provides information sufficient to carry out further simple, but useful, and instructive calculations

Chapters 7 and 8 are extremely valuable as they give a very clear description of the processes taking place in a reactor during start up, normal operation, shut down and power changes during normal operation The effects of fission product poisons, temperature changes and changes in the content of the fuel are discussed and illustrated by a number of figures The last chapter is on reactor kinetics and starts by considering the rate of change in the total number of neutrons assuming they are all prompt This is then followed by a very good description of the effects of delayed neutrons, assuming, to simplify the mathematics, that there is only one group

There are a few small transcription errors, which fortunately are fairly obvious, otherwise the printing and production are good and the price is reasonable The book can be thoroughly recommended to both students and professionals interested in the subject

K J DURRANDS

TOWARDS TAILOR-MADE POLYMER MOLECULES

Block and Graft Copolymers

By Dr E J Ceresa Pp xvi + 196 + 4 plates (London Butterworth and Co (Publishers), Ltd , 1962) 42*s*

NUMEROUS methods have been used to prepare block and graft copolymers The author has reviewed these in separate chapters (2–7 inclusive) according to the processes used, that is, transfer and addition, chemical, radical and irradiation, mechanicochemical, condensation and ionic These syntheses follow an introductory chapter outlining a clear and satisfactory nomenclature for describing the numerous products which can be classified as block and graft copolymers. Chapters 9 and 10, on the characterization and properties of such copolymers, reveal the chief difficulty in this field, that of obtaining a block or graft copolymer free from homopolymer As the author points out, only about 20 out of more than 2,000 block and graft copolymers synthesized or claimed have been fully characterized

Information on this topic is widely scattered Dr Ceresa has collected it together in one volume and has classified it very thoroughly The copolymer index at the end of the book is a most useful reference table, including roughly 900 of the block and graft copolymers so far synthesized, it is well cross-referenced to papers dealing with every copolymer listed The index is, of course, a guide to claims, rather than to completely characterized products

This book is a review of the literature and the author makes no other claim for it I feel that it could have been shortened quite appreciably without losing its admirable thoroughness Thus, the chapters on the preparation of copolymers contain numerous abstracts of experimental procedures, with references to the original papers As many of these are examples of the same class of synthesis, it is difficult to see what purpose is served by repetition Similarly, Chapter 8 (24 pages), dealing with industrial systheses, contains a list of published patent applications with an indication of the method used and the products claimed in each case. Most of these products are listed in the copolymer index and an extension of the references given in the index would have absorbed Chapter 8

To expect a critical survey of this field is to be optimistic in view of the limited data available Further progress should lead to interesting results relating the structure of macromolecules and their physical properties and will extend, still further, the contributions of polymer chemistry to our knowledge of free radicals and their reactions

In writing this very thorough review of the literature, Dr Ceresa has performed a service to those already familiar with the principles of polymer chemistry and who are interested in block and graft copolymers. The book is well produced and is remarkably free from printing errors—only four were noticed

S SMITH

PALÆOBOTANY OF *PTERUCHUS*

Bulletin of the British Museum (Natural History)

Geology Vol 6, No 2 On *Pteruchus*, a Microsporophyll of the Corystospermaceae By John A Townrow Pp 287–320 + plates 24–26 (London British Museum (Natural History), 1962) 20*s*

MICROSPOROPHYLLS called *Pteruchus* described thirty years ago by the late Dr Hamshaw Thomas and attributed to *Dicroidium*, are by far the commonest leaf in the Triassic of the southern hemisphere He placed the whole group of organs, leaf, microsporophyll and fruits, in the Corystospermaceae and included them in the Pteridosperms The present publication is the first thorough-going revision of these microsporophylls published since then

We may begin by noting with pleasure that Townrow describes no new species, but instead reduces some twenty ill-characterized ones to three He strongly supports Thomas's attribution of *Pteruchus* to *Dicroidium* and its close relatives, and tentatively attributes his three species to particular leaves His main contribution is, however, morphological and consists in restricting too wide possibilities Thomas regarded *Pteruchus* as a microsporophyll, that is a fertile leaf, and at the same time as an inflorescence, a kind of catkin bearing little bracts and fertile appendages This idea he put forward deliberately as involving no conflict but instead a triumphant illustration of his "New Morphology" This "New Morphology" is an extremely plastic treatment of the categories of 'leaf' and 'stem' which are considered not as fundamentally different but as alternative specializations of the *Rhynia*-like shoot system He went so far as to suggest that the poplar male catkin might have originated in such a form as *Pteruchus* and that *Pteruchus* itself was also to be compared closely with the leaf-like microsporophylls of Carboniferous Pteridosperms It is only fair to add that he did not claim fully satisfactory knowledge of *Pteruchus* and he allowed the possibility that it might be purely a microsporophyll or purely an inflorescence

Townrow eliminates most of this, *Pteruchus* he finds is entirely leaf-like in its origin on the stem and in the fine details of its branching Its symmetry is purely dorsiventral Any little photosynthetic outgrowths it bears are just small pinnules, borne in exactly the manner of pinnules and not like bracts It has no inflorescence-like feature at all This makes it fit comfortably into the Pteridosperm idea as that existed before the "New Morphology" However, within the Pteridosperms it stands by itself, and Townrow concludes that each of the 'Mesozoic Pteridosperms' seems remote from all the others We may hope soon to see a work from Townrow revising the seed-bearing organs of these strange plants

T M HARRIS

THE SOUTH AFRICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

DIAMOND JUBILEE CONGRESS

By A. C. BROWN

Department of Zoology, University of Cape Town

THE diamond jubilee of the South African Association for the Advancement of Science (usually referred to as S_2A_3) was celebrated in the University of Cape Town during the first week of July 1962. As befitted such an important event in the history of South African science, the planning of the Congress was considerably more ambitious than usual, and a number of scientists from Great Britain, France, America and Portuguese East Africa were invited to read papers and particularly to participate in a series of symposia. The organization of the congress was undertaken by a local committee under the chairmanship of Prof. Ronald Singer, a vice-president of the Association and associate professor of anatomy in the University of Cape Town. The congress was marred only by the recent death of Dr. J. S. Henkel, who was the last surviving foundation member of the Association and was to have been a guest of honour at the diamond jubilee celebrations.

It was most appropriate that the attention of members be directed to the history and achievements of their Association over the sixty years of its existence; this was done in several ways during the course of the congress, and by several speakers, including Dr. J. P. Duminy, principal of the University of Cape Town, in his presidential address on the "Challenges of Science to-day". Dr. Duminy pointed out that the rapid advances in science in South Africa and elsewhere have raised moral and ethical problems which are by no means to be lightly dismissed and that the scientist's obligations are still, and must always be, to the community of which he forms such an essential part. An article also appeared in the handbook issued to delegates, dealing with the birth of the Association—the outcome of a meeting of South African engineers in 1901—and with some of the men and women whose personalities have been an inseparable part of the Association over the years. The Association was patterned on the British Association for the Advancement of Science, which was represented at the Congress by Prof. R. W. James.

Concurrently with the senior congress, a junior congress was organized for advanced pupils of local schools. Many members consider the encouragement of scientific interests among high-school children the most important work of the Association, and the efforts of those who arranged the junior congress were indeed rewarded, for the numbers attending (320 from 27 schools) outweighed those attending the senior congress. Several junior members read papers which they themselves had prepared, and the general standard of these was very high. A very full programme was arranged for both junior and senior sections; from a scientific point of view, however, the highlights were certainly provided by the symposia.

A completely new departure for the Association was a symposium on palæontology. This was also the most extensive of the symposia and continued for most of the duration of the congress. The majority of the papers read dealt with vertebrate palæontology and the accent was on the reptiles and mammals of the South African Karoo. Never before has such a number of eminent palæontologists been present in any one place in South Africa at the same time, and members of the Association were not slow to take advantage of such a unique opportunity, the audience throughout being large and enthusiastic.

A paper which gave much pleasure and aroused considerable interest was that of Dr. A. W. Crompton, director of the South African Museum, who spoke on the origin of the mammalian lower jaw, drawing much of his evidence from *Diarthrognathus broomi*, an advanced therapsid Triassic mammal in which both the reptilian and mammalian jaw articulations were present. Dr. A. S. Brink, of the Bernard Price Institute for Palæontology, posed the question "How mammal-like are the mammal-like reptiles?" while Dr. J. Kitching, of the same Institute, discussed the fossil localities and mammal-like reptiles of part of Northern Rhodesia, concluding that "closely comparable conditions controlled deposition throughout central Africa in Karoo times and since these successions are broadly similar to those of the Republic of South Africa, such conditions were probably widespread over much of Gondwanaland". A guest from Paris, Mlle D. Sigogneau, read a paper on the classification of the Gorgonopsia, which she is studying in South Africa. Dr. E. H. Colbert, representing the American Museum of Natural History and an expert on Triassic reptiles, delivered two most interesting papers, one on the relationships of the Triassic reptilian fauna of southern Brazil—the other on the evolution of Triassic dinosaurs, ending with the suggestion that the so-called carnosaurs of the Triassic may possibly be a separate line of carnivorous pachypodosaurs, paralleled in later ages by the giant middle and late carnosaurs of the Mesozoic. The nineteen papers read at this symposium led to a considerable amount of lively and penetrating discussion, for which ample time had been allotted.

The symposium on marine biology was originally to have had as its theme "Food Relationships in Marine Environments", and though this plan had to be abandoned, several speakers delivered papers on this topic. The progress of marine research in South Africa—pioneered by John D. Gilchrist in the early years of the century—has indeed been rapid and has now reached the stage when the data and material collected over sixty years can be analysed with the view of greater understanding of the inter-relationships between different sections of the flora and fauna. Until recently, South African marine biology has been mainly concerned with the ecology of intertidal rock, estuaries, and shallow bays; this has proved an excellent apprenticeship for a programme which now pushed down to the edge of the continental shelf While benthonic studies are the concern mainly of Prof J H Day and his associates at the University of Cape Town, the marine plankton is being studied both at the South African Museum and by the Division of Fisheries A recently formed Department of Oceanography is also in operation, mainly interested in physical and chemical oceanography and providing valuable data which are being correlated with the distribution of the fauna and flora The results emerging from these studies—both with regard to distribution and to food relationships—are not only of considerable academic interest but also of urgent economic importance so far as the fishing industry is concerned Also under way is an investigation of the fauna of intertidal sandy beaches, an ecosystem which has been almost entirely ignored by South African zoologists until recently This oversight is probably due to the obvious paucity of sandy beaches as compared with intertidal rock (there are less than one hundred permanent inhabitants of intertidal sands described from the whole of South Africa), nevertheless this very paucity of species (though not of numbers) allows each one to be studied in great detail and the picture which begins to emerge may possibly be more complete than has been obtained from more popular intertidal environments Some attention was given to all the above aspects during the symposium, those taking part including Prof J H Day, Dr A de Decker, Mr J R Grindley and Mr F J R Taylor

A symposium on "Current Problems in the Behavioural Sciences in South Africa" was convened by Dr S Biesheuvel, president-elect of the Association and director of the National Institute of Personnel Research He opened the proceedings with a paper on the growth of abilities and character, which gave rise to much discussion and speculation "The Industrialization of an Indigenous People" was dealt with by Mrs Y Glass, while Prof K Danziger outlined "Some Social Psychological Aspects of Economic Growth" Another notable contribution was made by Prof C Wyndham, of the University of the Witwatersrand, who discussed the role of physiological factors in human performance This paper was of special interest to many delegates in that it supplemented to some extent an address given earlier in the week by Prof A W Sloan (Department of Physiology, University of Cape Town) in his capacity as president of the section dealing with human biological sciences Prof Sloan's topic was "Human Fitness" In an admirably clear and concise way he reviewed the methods of measuring human fitness and the standards of fitness encountered in college and university students in England the United States of America and South Africa It came as a surprise to many members of the large audience to learn that British standards of fitness are higher than those found in South Africa and very much higher than those of American students

In the middle of the congress week the delegates were transported to Stellenbosch University about thirty miles distant from Cape Town, to hear a symposium on "Fruit Research" The organizing committee had also arranged various entertainments and excursions, and the delegates were the guests of the Mayor of Stellenbosch at a luncheon given in their honour Those directing fruit research in South Africa are well aware of the need for a larger production of suitable foods for a rapidly increasing world population, indeed, this problem is particularly acute in countries such as South Africa where the majority of the population is underprivileged The development of high-protein foods to combat malnutrition among the lower income groups is thus of the greatest possible importance and is by no means being neglected by our food research institutes The organization of food research in South Africa was outlined by Dr C J B Smit, who also made a plea for closer co-ordination of food research activities in order to make the best use of existing facilities and personnel Although the Fruit Research Institute at Stellenbosch is largely concerned with applied and economic aspects of the subject, this does not imply that pure research has been ignored On the contrary, these scientists realize fully the necessity for research in all aspects of their subject This is illustrated clearly by Dr P G Marais's paper on the use of radioactive isotopes and ionizing radiations in agricultural research, the studies range from the essentially academic to those on the seasonal uptake of fertilizers and the irradiation of stored potatoes to prevent sprouting The symposium, covering these and other topics, did much to bring to the notice of fellow scientists, and the public as a whole, the valuable work being done at South African food research establishments generally, and by the Fruit Research Institute in particular

Two other symposia were held during the congress One organized by H M Astronomer at the Cape, Prof R H Stoy, dealt with astronomy in South Africa and covered not only recent developments in the observation of the southern sky but also the practical business of tracking man-made satellites both by optical and radio methods Of interest was the description of the Radio Space Research Station at Hartebeesthoek, near Johannesburg, which is operated by the South African Council for Scientific and Industrial Research and is designed primarily for the tracking of satellites and interplanetary research vehicles However, it is also expected that the Station will be able to make valuable contributions towards radioastronomy as such, when not required for its primary purpose Dr R Citron and Dr G Courtes, visiting scientists from the United States and France respectively, also read papers at this symposium

A short but intensely interesting symposium was held on "Early Man and his Environment" Prof J D Clark of Berkeley, California, discussed Pleistocene environments and culture change in Africa, while Dr R F Ewer, of Rhodes University, spoke on the contribution made by investigations of the associated mammalian faunas Among other aspects, she discussed the possible direct effect of mammals on human evolution, concluding that they provided an environment in which hunting skill could be perfected by easy stages and in which the development of such skill would be of great survival value Prof van Zinderen Bakker (of the University of the Orange Free State) and Dr G Bond (of the University College of Rhodesia and Nyasaland) both stressed the importance of different aspects of palæobotanical and geological studies in assessing the climate in which early man evolved The symposium was under the chairmanship of Mr R R Inskeep, senior lecturer in archæology in the University of Cape Town

In addition to the symposia there were the usual sectional meetings at which members of the Association read short original papers The standard of these papers was more variable than that of the symposia, but taken as a whole, they provided an interesting cross-section of science in South Africa to-day, the subjects ranging from the ecology of mangrove swamps to the decipherment of the Minoan scripts and from Stone-Age sites to the description of a versatile fraction collector Papers of particular interest included a report by Prof P V Tobias on the brain capacity of *Zinjanthropus*, a fossil ape-man from Tanganyika, and a paper by Dr Margaret Kalk on the occurrence of vanadium in tunicates, together with some suggestions concerning the intracellular mechanism which concentrates the metal and the possible part it plays in tunicate metabolism The difficulties of making a taxonomic study sound fascinating to non-taxonomists were admirably overcome by Prof H B Rycroft, director of the National Botanic Gardens at Kirstenbosch, in a paper on the history of the taxonomy of the Cape species of *Protea* during three and a half centuries, this was delivered as the presidential address to Section B (Botany) The presidential address to Section F (Humanistic and Social Sciences) was delivered by Dr M D W Jeffreys, who dealt with the cult of twins in Negro Africa Prof E Boné, official delegate from the University of Louvain, read a thought-provoking paper on human speciation as viewed in the light of palæontological species

Mention should certainly be made of the popular evening lecture, given this year by Prof D W Ewer, head of the Department of Zoology and dean of the Faculty of Science at Rhodes University, Grahamstown Prof Ewer's lecture was on "Mendelism and Macromolecules", but, as it was the intention to attract the general public, who are traditionally encouraged to attend this annual event, it was officially entitled "Brown Eyes, Blue Eyes, Short or Tall ?" We were much impressed by Prof Ewer's ability to explain the most complicated chemical phenomena with the utmost clarity Making brilliant use of models, he described the composition and replication of the chromosome and the nature and expression of the gene with such simplicity and logic that only the few of us who have lectured on this subject ourselves realized what penetrating and meticulous preparation lay behind his easy and almost informal delivery This was a fine and rare example of the art of lecturing and one which we shall remember for many years to come

A number of excursions organized for those attending the congress had a botanical bias and included a trip over the mountains into the Little Karoo, a route carefully planned to cross a maximum number of distinct types of floral habitat It is highly probable that following this route it is possible to see as many species and genera as over a similar distance anywhere in the world Prof H B Rycroft and Mr A V Hall acted as guides Though all the excursions were well supported, the most popular was a visit to the property of Dr S H Skaife, an authority on the life of social insects Parties were shown around Dr Skaife's laboratory, with its living colonies of ants and termites, and given first-hand explanations of the experiments which were being conducted The many people who generously welcomed parties to their laboratories, factories or private homes helped in no small measure to make this the outstanding congress it undoubtedly was It is generally felt that a standard has been set for future congresses in South Africa, and it is hoped that many of the innovations introduced at this diamond jubilee congress will become a regular part of South Africa's science time-table

BLAISE PASCAL (1623–62)

By Dr J ROSE

Vice-Principal, Coventry Technical College

"The heart has its reasons of which the reason knows nothing" (*Pensee*, 477)

IN the seventeenth century France was the most unified State on the Continent and numerically by far the strongest power in Europe Thanks to her large population and her wealth, France succeeded Spain as the dominant power on the Continent In some respects, however, seventeenth-century France was close to the Middle Ages, since it was essentially a semi-feudal State, based on a predominantly agricultural society The country was still in a transitional state from feudalism to Modern Age Socially, France was even more semi-feudal than seventeenth-century England, for the nobility and clergy were still privileged orders, divided in the legal and social sense from the artisans, peasants and traders, members of the inferior classes The peasant was at the mercy of his landlord in many respects, for example, taxation, marital status, residence, etc It was the peasant who bore the greatest share of the burdens of the country On the other hand, the middle class or *bourgeoisie* began to increase in importance at the expense of the nobility Owing to the general chaos in tax collection, some of the members of the *bourgeoisie* built up for themselves great fortunes, while acting as civil servants and advisers to the Government, and acquired by various procedures nobility status Indeed, the old social hierarchy based on birth was beginning to crumble, since the aristocracy suffered great impoverishment owing to their extravagant living Hence, under Richelieu and Louis XIV, only strict obedience to royal rule could allow them to survive and live in grand style, so that the scions of the great nobility were gradually transformed into flatterers and lackeys at the Court of "Le Roi Soleil" Even the revolts, known as the first and second Fronde, could not avert the evolution of France towards absolutism, which reached its height in the period 1661–85

As regards the position of the clergy, the Catholic Church presented a great contrast of piety and indifference, of deep dissensions and religious fervour The age of Saint Vincent de Paul, Fénelin, Bossuet and Pascal was also the period in which high offices of the Church were held by great noblemen and the sons of the King's ministers, the lives of most of them were thoroughly worldly, as shown by the memoirs of Saint-Simon In fact, the Church was a mirror of society, since in it the wealthy bishop and *abbé* looked down with contempt on the poorly paid and socially inferior parish clergy

In the first half of the seventeenth century, however, winds of change began to blow across France

The aristocracy and the rich were adorning the capital with imposing mansions, new districts were being built, and wide streets and spacious squares were laid out The religious awakening found its expression in new convents and monasteries, among them Port-Royal, presided over by the indomitable Mère Angelique, Saint Vincent de Paul began his work of charity and conversion Fashionable life glittered in the *salons*, while the open squares were being used as promenades by the gentry, *les honnêtes gens*, a species of cultivated gentlemen 'Honesty' in this context was identified with the art of 'pleasing' in the deepest sense of the word, that is, making oneself loved The *honnêtes gens* avoided everything pedantic and low, and appeared not to be interested in their profession or business. These notions and the glitter of the *salons* were, however, unknown to the mass of the people wrapped in poverty and ignorance

Despite the wretchedness of the masses, seventeenth-century France rings with great names of men of letters, for example, Corneille, Racine, Molière, La Fontaine and Boileau, and mathematicians, such as Fermat, Pascal and Desargues Their genius raised them above the spirit and conditions of the age, so that they were not the mirror of society The year of rampant ignorance saw the foundation of the Paris Academy of Sciences in 1666, four years after the Royal Society received its charter in England The Academy arose from an association of a group which used to meet at the cell of Father Mersenne, the originator of the Mersenne Numbers, who was responsible for spreading Galileo's teachings The original members included Descartes, Pascal, Fermat and Gassendi, whose commentaries on Epicurus revived the atomistic speculations of the early Greek materialists Mersenne acted as a sort of post-office, transmitting mathematical and scientific letters of his friends from one to another In fact, he founded a society of genuine scientists in 1635, the first centre of purely scientific life in Europe, and the members were Pascal's father and the mathematicians Roberval and Desargues He kept up an assiduous correspondence with Descartes in Holland and Fermat in Toulouse

The middle of the seventeenth century was the great age of mathematics in France In that country alone there were as many great mathematicians as Europe had produced during the preceding millenium The integral calculus grew out of the work of Cavalieri (1589–1647) and his successors, among whom one of the greatest was Pascal Indeed, Leibniz was influenced more by Pascal than by Newton in his mathematical thinking, so much so that we owe to Leibniz the record of parts of Pascal's work which would otherwise have been lost The theory of probability, projective geometry, the first calculating machines, and some remarkable predictions concerning quantum physics, saw the light of day in this age of greatness when the shackles of the Middle Ages began to disintegrate in the glow of the revival of critical thought The habits of mind were mathematical, and its methods were considered necessary for an exact philosophy Modern philosophy then began with Descartes, who built up a system by framing its axioms and postulates in such a way as to make philosophy acceptable to mathematicians Despite the great advances in science and mathematics there was, however, a manifest lack of its application to industrial processes, since industry was mainly conducted on traditional and small-scale lines

The life of learning was nearly completely cut off from the fashionable world and the people It was confined to groups or 'academies', in which various topics were discussed, ranging from physics to bibliography Moreover, these academies became the meeting places of the so-called free-thinkers These libertines, no idle scoffers, included such diverse attitudes as religious unbelief, philosophical detachment, or submissiveness to religious and political authority It was the sort of a *milieu* in which the mind was educated, and which influenced Pascal's attitude Even during Pascal's childhood, mathematicians and philosophers were his companions owing to his father frequenting such academies Indeed, Pascal's father reacted against the bonds of Aristotle's physics and thus spared his son the usual 'scholastic' training of the Middle Ages This is shown quite clearly in a letter addressed to Fermat in 1636 in which the value of experimenting and physical demonstration of proof was considered to be of primary importance in formulating a hypothesis

Pascal the Mathematician

Even in the age of Descartes, Fermat and Desargues, Pascal's mathematical brilliancy was unsurpassed At the tender age of twelve Pascal, stimulated by his father's refusal to allow him to study mathematics, devoted his spare time to geometry As a result of his deriving several leading properties of the triangle, his father repented and agreed to let him study Euclid and the conics of Apollonius Four years later Pascal published an original essay on conic sections based on a medieval geometrical theorem known as "l'hexagramme mystique", which states that if a hexagon is inscribed in a conic, the three points of intersection of pairs of opposite sides always lie on a straight line This idea was later taken up by Naclaurin, who introduced general methods for solving problems which cannot be attacked by the Cartesian procedures, in fact, he laid the foundations for the progress in pure science in the nineteenth century by Chasles, Clifford and Salmon, while the theory bore its finest fruit in the many-dimensional geometry of Segré

At the age of eighteen, in the year of Newton's birth (1642), Pascal made the first calculating machine in order to help his father in his tax-collecting activities The machine performed the carrying of tens automatically by means of wheels and ratchets In 1652 he sent one of his machines to Queen Christine of Sweden, the great patron of writers and scholars of the age A much more versatile machine made by Leibniz in 1671 was capable of adding, subtracting, multiplying and dividing, Pascal's denary notation having been replaced by a binary scale This invention, and that of a prototype of a wrist-watch, brought Pascal fame, so much so that this achievement was praised in prose, verse and sonnet, and a hundred years later Diderot described it in his *Encyclopedia* On the other hand, his health suffered greatly as a result of his labours The first symptoms of Pascal's life-long illness actually appeared at the age of one, probably due to a malformation of his skull There was a gradual worsening in his health, and the constant studies, as well as the endless controversies with his contemporaries, took their toll

Pascal's gift as a mathematician was overwhelming While lying awake and suffering in the last years before his untimely death at the age of thirty-nine, he established the chief properties of the cycloid by a brilliant geometrical argument This particular problem had baffled Galileo and Descartes, while Pascal, by using "the method of indivisibles", recently invented by Cavalieri, put the mathematics of this curve in its proper perspective within eight days In his letters to Sluse, Carcavi and Huygens dealing with the cycloid, Pascal laid the foundations of integral calculus

As a geometer Pascal ranks as one of the great of the millenium This is especially evident in his contribution to projective geometry in which the object is to discover those properties of figures which are invariant under projection The technique is one of the most elegant parts of mathematics, and its fascination extends to the historical origins in the work of Renaissance artists In this field Pascal was urged by the architect and engineer Desargues to investigate the properties common to sections of projections The theorems derived by Pascal and Desargues showed that there are significant properties common to sections of any projection of a given figure, and thus interpreted to some extent certain features of painters' work Owing to the antagonism exhibited towards projective geometry by the mathematicians of the period, with the honourable exception of Descartes, Desargues abandoned this field of geometry, and his publication was lost Fortunately, a book published in 1648 by Desargues's pupil, Bosse, who reproduced his master's results, was rediscovered in 1804, while Pascal's work published in 1640 remained unknown until 1800 The work of these two geometers thus lapsed into obscurity until the nineteenth century, when Chasles picked up by accident in a bookshop a copy of Desargues's work written by his pupil, P de la Hire It is also of interest to note that analytical geometry created by Descartes and Fermat, and the calculus, invented chiefly by Leibniz and Newton, proved extremely useful in the physical sciences, while scientists and mathematicians displayed no interest in Desargues and Pascal with their novel and baffling terminology Indeed, the great success of Descartes's analytical geometry with its "insistent clatter of the co-ordinate mill" almost completely diverted attention from pure geometry, so that it languished for two centuries, especially since Newton, Euler and Lagrange continued in the Cartesian tradition In our times, projective geometry has had an important bearing on mathematical and physical sciences Thus the emphasis on invariance of scientific laws, as recognized by the theory of relativity (the laws of the Universe varying from one observer to another) is no stranger to the mathematical physicist or geometer, since the concept of invariance plays a prominent part in the work of projective geometry

So far as algebra is concerned in the modern sense of the word, Pascal might be considered as one of its founders Following discussions with Fermat about games of chance and probability, Pascal adopted the arithmetic triangle, a device used earlier by Napier, to the solution of problems involving combinations of given things In fact, he utilized the diagonals of the triangular of numbers for working up the binomial expansion of $(a + b)^n$, where n is a whole number, thus introducing a geometrical pattern into configurations of numbers and creating higher algebra Newton investigated this pattern further and thus discovered the binomial theorem in its general form, while Bernoulli, Euler and Cayley, very much later, built on the foundations laid down by Pascal in 1653

The year 1654 witnessed the birth of the theory of probability, when Fermat formulated its fundamental principles in a short correspondence with Pascal This discussion had actually arisen as a result of a request by two gamblers disputing the distribution of winnings in an unfinished game, thus, to use a metaphor, the probability theory has been born under a gaming table to become the dictator of modern science Pascal went even farther in his famous wager with the Devil Since the expectancy of winning a prize in a lottery is the value of the prize multiplied by the probability of winning it, though the average sinner's probability of winning eternal bliss may be very small, the prize is so great that it will pay him to take a chance to reform his ways and live a good life Furthermore, Pascal asked whether probability itself is probable, thus anticipating some of the postulates of quantum physics

Despite Pascal's preoccupation with theological activities at that time, he scarcely interrupted his scientific pursuits He had kept in touch with Roberval and others, and in 1657 he entered into correspondence with the mathematician Sluse in order to solve certain problems of the geometry of curves

Contributions to Physics

As a result of discussions with P Petit, the commissioner of ports and fortifications, Pascal became interested in Torricelli's experiments on vacuum He devised a series of experiments involving tubes of various sizes and shapes, in combination with diverse liquids, for example, mercury, oils, wine and water Pascal found that the space in the Torricellian tube above the liquid was indeed a vacuum, thus eliminating the Aristotelian axiom that Nature abhors a vacuum His experiments became widely known in scientific circles in France and abroad It was the fear of conceding originality to others that prompted Pascal to publish *Nouvelles Expériences touchant le Vide* in a great hurry in 1647 His postulate of the existence of a vacuum was a revolutionary step, since even the great Descartes assumed the existence of "subtle matter" in the Torricellian space, in accordance with the medieval principle that Nature abhors a vacuum In addition, he devised a series of experiments in the period 1647–48 in order to demonstrate the truth of Torricelli's assertion that the height of the column of mercury in Torricelli's tube is balanced by the weight of air The *Traité de Vide*, published in 1654, summarizes this work His writing is also notable for its clearness and brevity, in contrast to the verbose Latin dissertations of his scientific contemporaries

Pascal then applied himself to the study of liquids in general and formulated the law that the pressure exerted anywhere on a confined liquid or gas is transmitted without loss in all directions throughout that fluid These researches led to the manufacture of the first syringe and the understanding of the relation between barometric pressure and height above the Earth's surface Indeed, the first calculation of altitude was made by Pascal in 1648 by studying the heights of columns of mercury in Torricellian tubes at various places

Pascal as Thinker and Theologian

As already described, religious life in seventeenth-century France was undergoing a profound change Outward respect for religious observance was combined with a lack of inner piety, while the scholastic aspect of theology was neglected in favour of delving into Biblical texts and non-metaphysical contemplations. In order to avoid any possible conflicts between reason and faith it was assumed that anything which is the concern of faith cannot be the concern of reason. This age is also marked by a religious revival, by the emergence of the doctrines of Saint-Cyran and Jansenius, and by the Jesuit–Jansenist controversy. The spirit of this upheaval penetrated into the very citadels of the agnostics, so that many great families abandoned the life of dutiful religious practice in favour of inner piety, austerity, penitence and virtue. Thus, the brawling and fiery brothers Deschamps, who later exerted a great influence on the Pascals, became 'converted' and devoted their lives to works of charity. Blaise Pascal experienced his first 'conversion' in 1640 by becoming an ardent Jansenist, but this did not detract him from scientific pursuits, though the Jansenist tradition did insist on abandoning the desire for knowledge, since the latter was equated with intellectual arrogance. His zeal in matters religious was, however, quite strong, as shown by his spirited attacks on some eccentric theses propounded by the Capucin friar Jacques Forton, who tried to eliminate the mysterious element in Christianity by pushing to the extreme limits the agreement between reason and faith. At the same time, scientific integrity prompted Pascal to indulge in a bitter argument with the Jesuit Father Noel, who defended the physics of Aristotle and refuted Pascal's interpretation of Torricelli's experiments.

Pascal's life was divided between a deep attachment to science and a perfect submission to his faith. His enemies ranged from the Jesuits to Voltaire, but his inner piety and religious sentiments were unimpeachable. This is clearly shown in his letters written in the period 1647–51. In one of these he described marriage as "most dangerous and the lowest of the conditions of life permitted to a Christian", though he apparently contemplated matrimony for some time, at least in order to improve his finances. Although he cultivated the society of 'free-thinkers' and he felt a deep passion for science, popularizing his discoveries in lectures at various gatherings, he felt increasing uncertainty and confusion, in the words of his sister Jacqueline, "he has experienced a great contempt for the world and a great distaste for people who compose it". All this led to the 'second conversion' on the night of November 23, 1654, which culminated in a mystical ecstasy, contrite humility and fervent exaltation, as shown by the text of the "Mémorial" which he carried inscribed on parchment around his neck. He renounced marriage, but did not withdraw from the world. In fact, this event was followed by a brilliant series of letters, known as *Les Provinciales*, in which he pleads the defence of the Jansenist theology against the Jesuits and the doctors of the Sorbonne. Though Pascal did not belong to Port-Royal, the citadel of Jansenism, in a formal sense, he was one of its effective allies.

The 'Provincial Letters'

One of the results of the Reformation in France was the emergence of a strong Counter-Reformation movement. The protagonists of the latter movement were, however, divided among themselves, and a number of groups could be distinguished. The members of the Society of Jesus were the first to enter this intellectual battlefield. They sought to reconcile traditional Church doctrine with intransigent modernism. On the other hand, the Jansenists (led by Bishop Cornelius Jansenius, 1585–1638, and Saint-Cyran, 1581–1643) abandoned modernism and preferred the dogmas of the ancient Church. They believed that in Saint Augustine there was an antidote to lax morality and collapsed standards. A profound pessimism appears to invade the Jansenist doctrine, since they assumed that from the moment of Adam's fall man has lost his will to do good, so that he is in need of omnipotent divine grace to lead a good life, these teachings are contrary to Jesuit principles according to which man has absolute liberty to choose good or evil, divine grace being a mere prompting, and not a compulsion. While the Jesuits were preoccupied with 'minimal' levels of living, sufficient to attain salvation, the Jansenists demanded total submission to God and maximum perfection. Jansenism thus represented an intense reaction against religious abuses and the Jesuitic teachings because of the latter's opportunism and spirit of compromise. Some of these teachings were published by Jansenius in *Augustinus* in 1640, the book was later condemned by Pope Alexander VII in 1657.

Though the convent of Port-Royal became the citadel of the Jansenists, it did not always follow the doctrine with exactitude. Great controversies arose in the 1640's, so much so that the Pope himself became involved, and the Sorbonne was asked to sit in judgment on certain aspects of the Jansenist doctrine. The *Provincial Letters*, which were placed on the *Index* in 1657, form the defence of Jansenism during the protracted proceedings at the Sorbonne. It is a collective work by Pascal and other theologians, an anonymous and clandestine book, addressed to all men of good will. In order to interest the widest possible public Pascal sought to enliven it with wit and endow it with a clarity of style, exposition and composition. Parts of the letters are also concerned with fierce battles with Jesuits. Pascal seeks to define the relation between God and man, and considers the problem of human responsibility, he opposes the two conceptions of human personality, as defined by the Jesuits, by delving deeper into man's intimate selfhood corrupted by original sin. At the same time, he attacks their morality founded on casuistry, using irony, comedy, indignation and vehement eloquence to smash his opponents. For his pains the enemies of Port-Royal called him a heretic, slanderer and Calvinist. As a result of this spirited reaction and the persecution of the Jansenists, Pascal had to adopt in his last letters a more conciliatory attitude, to some extent, the ideas propounded in his last letters departed from the fundamentals of Jansenism.

In the *Provincial Letters* Pascal reveals to some extent his true nature. He shows himself to be the religious apologist seeking deep conversion of sinners, he uses scientific methods and appeals to experience wherever possible. Mystical qualities are sometimes infused with polemical vehemence, bias and a lack of charity so much so that Chateaubriand called him "a slanderer who had genius". In his letters there is a deep anxiety of the soul, an aspiration after the infinite a spiritual ferment, an attack on lax moral theology prevailing in the seventeenth century—all this clothed with magnificent prose. The points raised in the letters are elaborated in greater detail in *Ecrits sur la Grâce*.

The impact of Pascal's writing on the cultural history of France was tremendous, though at the

Important Research Journals

Electronics Reliability & Microminiaturization

Editor-in-chief **G. W. A. DUMMER.**
Editors **DR. P. J. FRANKLIN,** *Washington D.C.*, **DR. J. W. GRANVILLE,** *Royal Radar Establishment, Great Malvern*, **DR. A. RADEMAKERS,** *Eindhoven*, **C. M. RYERSON,** *New Jersey*

A new international research journal which brings together papers concerning reliability and microminiaturization which at present would appear in journals not specializing in these subjects. The subject matter covers the practical, theoretical and statistical aspects of reliability, and the design, construction, engineering, testing and theoretical appraisal of microminiaturization techniques and systems.

Some Contributors and Papers

E D VAN REST—The statistical approach to the improvement of reliability, J C TURNER—Reliability and operability of systems of components in series and in parallel, A A SORENSEN—Digital-circuit reliability through redundancy, G W A DUMMER—A review of British work on microminiaturization techniques, S F DANKO—The micro-module approach to microminiaturization, G J SELVIN—Microcircuitry special considerations for military quality systems Published quarterly

Life Sciences

Regional Editors

A. C. ALLISON, *Medical Research Council, Mill Hill, London*, **B. B. BRODIE,** *National Institution, of Health, Bethesda, Maryland*, **A. I. OPARIN,** *Moscow*, **Y. ZOTTERMAN,** *Kungl Veterinarhogskolan Stockholm*

This unique journal acts as an international forum for the rapid dissemination of new and significant information in the life sciences In this way discoveries and concepts in biology will catalyse research in other branches

Some Contributors and Papers

R MICHEL ZILBERSTEIN—Reserpine- and serotonin-estrogen interactions on the uterus of the rat, TH SZABO—The activity of cutaneous sensory organs in *Gymnarchus niloticus*, M M R K AFRIDI and E J HEWITT—Induction and stability reductase in tissues of higher plants, I S LONGMUIR—The effect of hypothermia on the affinity of tissues for oxygen, J NECINA—Antagonism between L-α-methyl DOPA and reserpine, R B ARORA, C N MATHUR, Y R SAXENA and T K TARAK—Urinary excretion of 5-hydroxy indole acetic acid and catecholamine in healthy Indian subjects and in patients of acute myocardial infarction Published monthly

Petroleum Chemistry U.S.S.R.

Translation Editor, **D. L. SAMUEL,** B Sc, A R I C, F Inst Pet

This important publication—the English edition of the Russian journal "Neftekhimiya"—is invaluable to all scientists and engineers working in the field of petroleum chemistry who wish to keep in touch with the work of their Russian colleagues

Some Contributors and Papers

YA M PAUSHKIN and A G YUZVYAK—The production of vinylcyclohexane and styrene from butadiene, YA T EIDUS and K V PUZITSKII—Synthesis of esters by the carbalkoxylation of olefins with carbon monoxide, L A MUKHAMEDOVA, M KH BAIBUROVA, T M MALYSHKO and M I KUDRYAVTSEVA—The synthesis and properties of dialkyl epoxyhexahydrophthalates, A A RYBNIKOVA, I N TITS-SKVORTSOVA and E NORDOV—The hydrogenolysis of organic sulphur compounds on an aluminium-cobalt-molybdenum catalyst, N N BEZINGER, M A ABDURAKHMANOV and G D GAL'PERN—The nitrogen compounds in petroleum, 2 Separation of the nitrogen bases from organic sulphides, B V IOFFE and O YE BATALIN—New data for the dispersimetric determination of aromatic hydrocarbons Published quarterly

Topology

founded by J H C WHITEHEAD, *Oxford*

Editors, **M. F. ATIYAH,** *Mathematical Inst, Oxford*, **R. BOTT,** *Department of Mathematics, Harvard University*, **F. HIRZEBRUCH,** *Mathematical Institute, University of Bonn*, **I. M. JAMES,** *Mathematical Inst, Oxford*, **R. THOM,** *Mathematical Institute, University of Strasbourg*

This outstanding journal will be of great interest and value to all mathematicians in both the academic and industrial fields Special emphasis is laid on topology and its related subjects, using topological techniques such as homological algebra, Lie groups, differential geometry and algebraic geometry

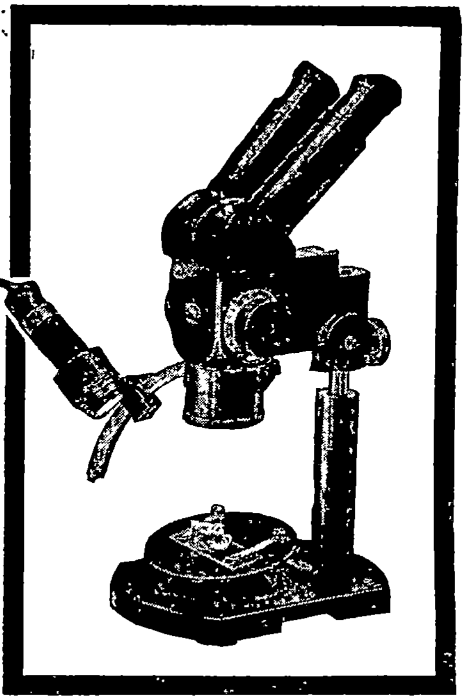
Some Contributors and Papers

M F ATIYAH and F HIRZEBRUCH—Analytical cycles on complex manifolds, J F ADAMS—H-spaces with few cells, J F ADAMS—Vector fields on spheres, S EILENBERG and J C MOORE—Limits and spectral sequences, J H WILLIAMSON—Remarks on the plancherel and pontryagin theorems Published quarterly

Inspection copy and details of subscription rates will be sent on request

PERGAMON PRESS

Headington Hill Hall, Oxford



ZEISS

STEREO MICROSCOPE

This microscope incorporates automatic drum-change magnification which gives a range from 4× to 100× without the need to re-focus on altering magnification. The fixed working distance is 4″. Accessories are available for transmitted light and photomicrographic work. Ideally suitable for the chemist and metallurgist in all forms of research work where simple and rapid operation is essential.

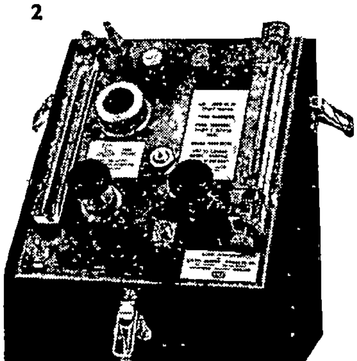
For more accurate measurement of Dew Point

1

2



1. DEW POINT APPARATUS

For measuring dew point or relative humidity of air in large or confined spaces. The design ensures a rapid appearance and disappearance of the dew formation, while an insulated thermometer enables accurate temperature reading to be taken. Write for leaflet 792/N.

2. THE ALNOR DEWPOINT METER

Enables dew or frost points to —80°F (—62°C) to be measured easily and quickly. The gas to be tested is compressed into an observation chamber where the pressure is suddenly released with near-adiabatic conditions, resulting in a cloud of water droplets being formed. The dew or frost point is determined by the use of a simple calculator. Write for leaflet 896/N

CASELLA LONDON

Clerkenwell 8581 (6 lines) *Members of the Scientific Instrument Manufacturers' Association of Great Britain and the British Scientific Instrument Research Association.*

time his defence of Jansenism was of no avail Though his health declined rapidly, he pursued his scientific inclinations He invented a new method of teaching reading for use in the Port-Royal schools in 1655, and established in Paris a regular omnibus service—the first of its kind His illness, however, grew worse, and he died on August 19, 1662, without disavowing his past life or beliefs (J Mesnard, *Pascal* 130, Harvill Press, London, 1962) Among the many manuscripts left, some of them unfinished, was a collection of notes, which were given the title *Pensées* by the first editor, these notes appear to be a product of reflection, suffering and deep insight The actual arrangement of these fragments is not known with certainty, despite many editorial attempts (*loc cit*, 134) In this 'tract for the time' Pascal seeks to awaken in the 'free-thinker' a religious sense, an inner ardour and æsthetic appreciation of the Christian faith by a skilful mixture of rational demonstration, emotional appeal and sense of drama He attacks the unbeliever by asserting the necessity of reason submitting itself to the mysteries of faith, as defined by the theologians of Port-Royal This Apology is based on The Bible and also on the writings of his contemporaries, the Jansenists, Descartes and various Christian apologists The work is original and coloured by a powerful imagination, it is written in the style of a scientist and mystic, and it helped to keep alive in France a certain Christian sensibility among unbelievers

Pascal as Man and Artist

Pascal meant different things to different people To the eighteenth-century Condorcet he appeared to be an agnostic to the Romantics he was the type of an anguished man, Claudel and Aldous Huxley looked at him as a sick man and a life-hater, respectively, some modern thinkers view him as a Christian humanist, on non-believers of all ages Pascal exerts a fascination owing to his scientific achievements and ruthless analysis of the world in terms acceptable to the free-thinker, to certain existentialists he is the inspired founder To the French he is the father of modern prose and a superb artist

This diversity of opinion may perhaps be ascribed to the very perplexity of Pascal's personality He was a bundle of contradictions, charitable in daily life, but merciless in controversy, truthful, but a cunning advocate, deeply religious, but a defiant opponent of certain aspects of established beliefs, a humble Christian, though a dauntless sceptic, man of science and high society, though an ascetic and of simple tastes—a veritable cauldron of opposing tendencies He combined the pursuit of science and attention to the fashionable world with austerity and anguish A neurotic racked by pain of a life-long illness, a deep believer and rational theologian Violent and merciless towards his adversaries, somewhat arrogant, conscious of his genius and impetuous as a religious apologist, but with a passion for truth and goodness He could experience great ecstasy, but preserve a lucidity of reason Even in the biography written by his sister, Pascal gives the impression of being hot-tempered, irascible, obstinate and discourteous He was a child of a troubled age, of an epoch of religious and social upheavals, an age of Copernicus and Galileo, and of cruel religious wars

As a thinker Pascal was original in his emphasis on the primacy of the experimental method, contrary to his contemporary Descartes, who asserted that experiments merely confirm mathematical deductions. He discarded deductive reasoning in science and theology, in both, reason plays a limited part Experience reveals two classes of facts, religious and scientific, independent of each other In philosophy the fundamental role of experience is equated with the primacy of existence, though man by considering his own existence realizes the necessity of the divine filling a vacuum in his mind, without God, man is wretched and powerless However, the heroic element in man allows him to rise from the slough of despair and acquire greatness by turning to God, who clarifies human thought, so that man perceives the truth True religion, according to Pascal, can only consist of love of God, hence ceremonial rites lose their importance, as religion becomes based on a personal link between God and man on the path to perfection Though Pascal was condemned posthumously as a Jansenist and heretic, his reputation as a theologian grew, for he diagnosed the anguish of the soul and prescribed the remedy

Pascal was a superb man of letters He eschews everything that smacks of 'false beauties', specialization and 'unnaturalness' and he paints passions in their natural colour and distinct order His style is a blend of a poet and scientist As a poet he creates images by using original metaphors, a sense of rhythm and superb lyricism, his thought, however, shapes itself in a scientific mould His life is a desperate attempt to try to comprehend as he put it "I know nothing about all things" There is a profound unity in his life and work He expresses the aspirations of the ages, the spirit of restless generations in search for an ideal and concrete reality Pascal sought truth in life, religion and science, so that his vocation was to run from one high place to another to light the fires (Guitton, J, *Pascal's Pensées*, 11, Librarie Générale Française, Paris, 1962)

SOME RECENT MEASUREMENTS OF CÆSIUM-137 AND ZIRCONIUM-95 IN HUMAN BEINGS

By J. RUNDO and D. NEWTON

Atomic Energy Research Establishment, Harwell, Berks

MEASUREMENTS of the mean level of fall-out cæsium-137 in a small group of control subjects have been made at this Establishment since early 1956, using body radioactivity measurement with scintillation γ-ray spectrometry[1] The results of such measurements to September 1960 have been reported[2] Cæsium-137 has been the only γ-ray emitting fission product detectable except during and very shortly after periods of nuclear test explosions, when iodine-131 was present in thyroid glands However, we have had occasion to suspect the intermittent presence of an emitter of 0 75-MeV γ-rays

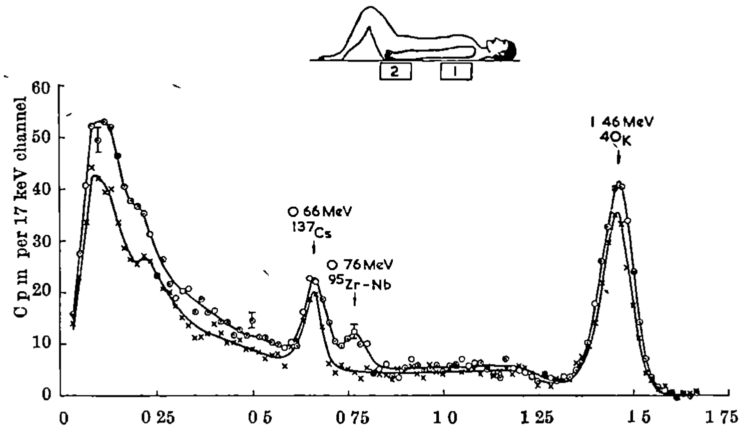

Fig 1 Gamma-ray spectra from subject *M* measured on April 24, 1962, with a crystal of sodium iodide (Tl) 23 cm in diameter by 15 cm thick

(presumably zirconium-95/niobium-95) during periods of intense fall-out (for example, the spring of 1959), when clothing contained easily detectable amounts of these nuclides The modest sensitivity and energy resolution of our equipment[1] precluded accurate energy measurement of the suspected contaminant *in vivo* and also of localization in the body In this article we are presenting the results of our measurements of fall-out cæsium-137 since September 1960, we also wish to report the recent detection of radiation from human lungs which we attribute to inhaled zirconium-95/niobium-95. During April and May 1962 we used a crystal of sodium iodide (Tl) 23 cm in diameter by 15 cm thick for measuring the cæsium-137/potassium ratios of our control subjects As we suspected the presence of fission products in lungs, two 20-min measurements of body radioactivity were made at each observation, the first was with the centre of the crystal placed under the mid-point of the sternum of the supine subject and about 2 cm below the back, while the second was with the crystal under the subject's sacrum as indicated in the inset of Fig 1, which shows the two γ-ray spectra obtained from subject *M* In addition to the prominent photo-peaks at 0 66 MeV and 1 46 MeV due to cæsium-137 and potassium-40 respectively, the first spectrum shows a well-defined photo-peak at 0 76 MeV which we attribute to zirconium-95/niobium-95 in the lungs To eliminate the possibility of this activity being in clothing or on the skin, all subjects showered immediately before the measurements and changed into clean clothes which had been stored in plastic bags The counter background was measured either immediately before or after the subject with a distilled water phantom in position on the stretcher, 'dressed' in the clothes worn by the subject All persons examined have shown evidence of this radiation from the lungs, including a 6½-year-old girl

Caesium-137 In order to determine the cæsium-137/potassium ratios *in vivo* the following measurements were made Spectra from known amounts of cæsium-137 and potassium in solution in a phantom were measured separately and these were used to estimate the cæsium-137/potassium ratio from the results obtained at the second measurement on each subject, that is, those which showed no indication of a peak at 0 76 MeV Because of the geometrical arrangement of subject and detector the absolute values of potassium and cæsium-137 were not considered reliable, but in most cases the values of their ratio were consistent with the values obtained for the same subjects measured by our usual method[1] in January 1962, and they were thought to be correct to within the statistical error of not more than ± 2μμc cæsium-137/g potassium The results of all measurements of the mean cæsium-137/potassium ratios in the control group since September 1960 are set out in Table 1, these values are plotted in Fig 2, where the earlier measurements (from February 1956) are included together with those of the subjects with the highest and lowest values of the ratio The values for January and April 1962 call for comment as zirconium-95 was present on both dates The scale of cæsium-137 content at the right of Fig 2 is approximate and applies only to the average values, and not to the measurements on subjects *C* and *R* This is because the potassium contents of these subjects were not the same as the average for all the control subjects, thus the cæsium-137 content of subject *C* in July 1959 was 16 3 mμc (99 μμc /g potassium) while the scale of Fig 2 indicates only 14 5 mμc The mean value for April 1962 was determined from the measurements with the single large crystal as already described All the γ-ray spectra from the subjects measured in January 1962 were averaged and a small photo-peak due to zirconium-95/niobium-95 at 0 76 MeV was then apparent (it was not as prominent as shown in Fig 1 because of the much less favourable geometry) The mean potassium content was calculated and its contribution in the region of the cæsium-137 and zirconium-95 photo-peaks was determined and subtracted The mean cæsium-137 content was then determined by trial-and-error, and its spectrum was subtracted, leaving a surplus counting-rate due to the average zirconium-95 content (see below)

By October 1961 the mean cæsium-137/potassium ratio had decreased to a lower value than at any time since our measurements began The rate of decrease from March 1960 indicated a halving time of about 16 months, which is very similar to the value found by other workers[3] This time is much longer than the

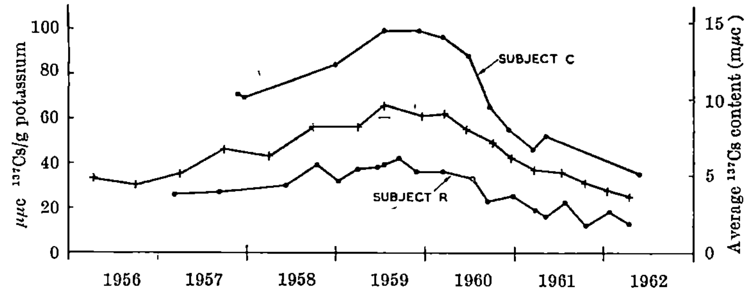

Fig 2 Mean cæsium-137/potassium ratios in a group of control subjects from 1956 to April 1962, and the ratios for subjects *C* and *R* The scale of cæsium-137 content at the right is approximate and applies only to the mean value of the group

biological half-life of cæsium in man (our data, which will be described in detail elsewhere, indicate an average value of about 110 days), showing that the daily intake is not directly proportional to the rate of fall-out, which decreased faster than did the cæsium-137/potassium ratios *in vivo*

Zirconium-95 In the average spectrum from the controls measured in January 1962, the counting-rate at 0 76 MeV, after subtraction of contributions due to potassium-40 and cæsium-137, was attributed to zirconium-95/niobium-95 The best estimate which we can make of the average content is about 300 μμc (total γ-ray activity at 0 76 MeV)

To estimate the amounts of zirconium-95 in the lungs of the subjects measured in April 1962, we used special chest phantoms similar to that described by Miller[4] These were constructed with sheets of 'Mix D' phantom wax[5], with air-spaces to simulate the low density of the lungs, a standard source of zirconium-95 was placed in turn in each of the air spaces and all the spectra were added together in order to simulate the effect of a distributed source. This was repeated for each of several phantom thicknesses (15–24 cm) to cover the range of chest thicknesses of the subjects The spectrum obtained using the 20-cm phantom, together with the spectra from the normal cæsium-137 and potassium phantoms, were used to calculate the cæsium-137/potassium ratio and a value for the lung content of zirconium-95 by a computer method of least squares analysis[6] Because the shapes of the spectra at low energies from the zirconium-95 showed considerable variations with the various phantom thicknesses, and because we suspected the presence in the spectra from the subjects' lungs of contributions from ruthenium-103 and cerium-141 (0 5 MeV and 0 145 MeV quanta respectively), the least squares fitting was confined to the energy range 0 57–1·675 MeV, but the computer was programmed to calculate the spectrum over the entire energy range measured (0 025–1 675 MeV) The cæsium-137/potassium ratios were in excellent agreement with those calculated from the results of the second measurements

An alternative method was also used to determine the amounts of zirconium-95 in some of the subjects, the spectrum obtained with the crystal near to the subject's sacrum was normalized in the energy range 0 83–1 675 MeV to that obtained with the crystal close to the lungs, and the spectral difference (energy range 0 63–0 83 MeV) was attributed to zirconium-95, the amount of which was calculated The statistical errors were considerably greater than in the computer method, but the results from the two methods were in good agreement except where relatively large normalizing factors were needed

To allow for the differences between the chest thicknesses of the subjects and the thickness of the chest phantom chosen as standard, the estimated zirconium-95 contents were multiplied by appropriate correction factors deduced from the measurements with the various phantoms These corrections were all small (< 20 per cent) except in the case of the child The results for 15 subjects are set out in Table 2, where the values for zirconium-95 are the total γ-ray activities at 0 76 MeV Only the statistical error is indicated, there may be a systematic error due to the calibration method, but we have not been able to assess this In calculating the values for the concentrations of zirconium-95 in the lung it has been arbitrarily assumed that the mass of the lung is 1 43 per cent of the body-weight The radiation dose-rate from an average concentration of 0 35 μμc /g of zirconium-95 with niobium-95 in equilibrium is 0 11 μrad/h, if the zirconium-95 is distributed uniformly throughout the lung, but this would not be valid if the zirconium-95 were on a few relatively large particles As we know nothing of the distribution within the lung, the values of 0 05–0 16 μrad/h for the radiation dose-rates to the lungs of the individual subjects are lower limits For comparison, the dose-rates in soft tissues (presumably including lung) due to the naturally radioactive potassium-40 and to the average level of fall-out cæsium-137 are 2 2 μrads/h and 0 49 μrad/h respectively Thus, although the average dose-rate from the zirconium-95 is twice that from the cæsium-137, it is still small compared with the dose-rate from natural background

* Total γ-ray activity at 0 76 MeV

† Lung weight assumed to be 1 43 per cent of gross body-weight

‡ Child aged 6½ years

Because the major part of the counting-rate at low energy (< 0 57 MeV) was due to potassium-40 and cæsium-137 it was not possible to detect with certainty the presence in the spectra of photo-peaks at 0 5 MeV and 0 145 MeV, due to ruthenium-103 and cerium-141 respectively, although there were indications of these peaks in the spectra from most subjects Attempts to improve the statistics by averaging spectra, or by averaging the differences between observed and computer fitted spectra, were not successful in demonstrating statistically significant photo-peaks at these energies However, the presence of ruthenium-103 and cerium-141 in the lungs must be assumed because of their presence in the air[7] and in human excreta[8], these nuclides will increase the dose-rates to the lungs It is interesting to note that the average lung content of zirconium-95 of three subjects was 28 times their daily fæcal excretion of this nuclide[8], implying a biological half-life in the lung of about 19 days

Finally, we may note that the amounts of zirconium-95 found by us are similar to the amounts found by Schonfeld *et al.*[9] in the lungs from three subjects examined *post mortem* in Vienna in the Spring of 1959.

Note added in proof. The cæsium-137/potassium ratios *in vivo* in July 1962 were significantly higher than in April. Our provisional results indicate a mean value for six subjects of 35 μμc cæsium-137/g potassium; the mean value for the same six subjects was 29 μμc cæsium-137/g potassium in April. The average lung content of zirconium-95 for these subjects declined from 357 μμc in April to 217 μμc in July (provisional result). From their analyses of human lungs obtained *post mortem*, Schonfeld and his colleagues (paper presented at the third International Congress for Hygiene and Preventive Medicine, Vienna, May 27–30, 1962) calculated zirconium-95+niobium-95 contents of up to about 200 μμc in February 1962. This is similar to our average value for January 1962.

FUTURE OF OPTICAL ASTRONOMY*

By PROF. D. E. BLACKWELL

Savilian Professor of Astronomy, University of Oxford

I BELIEVE that optical astronomy in Great Britain has now reached, for virtually the first time in its history, a critical stage, and its actual survival is not something that can just be taken for granted without further thought. Physics is studied in universities and in Government and industrial laboratories; but with two exceptions, optical astronomy is studied almost entirely in university laboratories only, and its future largely depends on the attitude of the universities. Too often, the attitude the world over is that an observatory is a place to which one can take one's children on a fine Saturday night. By tradition, astronomers are the most hospitable of all scientists. But the danger of such hospitality is that the visitor sees an almost non-existent aspect of the professional work of an observatory, demonstrated with a telescope perhaps more than a century old, and comes to believe that the astronomer lives in a dream world in which he gazes at the Moon and planets and is constantly watching for the appearance of a new star. Or, if he does not wholly believe this, he thinks of an astronomer as a Victorian scientist using Victorian methods and instruments in a Victorian institution. I do not need to emphasize how damaging such an attitude is to the proper development of astronomy in the universities.

In the early nineteenth century astronomy was receiving whole-hearted support from Government, patron and university, and by the time that physics became established as a proper subject of study in the universities, astronomy was already a firmly established subject, and from then on the two flourished and developed side by side quite independently. This is the beginning of the present unfortunate distinction between physics and astronomy, or between physics and astrophysics, which is often exemplified by the presence in a university of an observatory quite distinct from a physics laboratory. Although each had much to learn from the other they were always, and still are, treated as two entirely separate subjects. In reality, of course, modern astronomy is simply a branch of physics just as much as is low-temperature physics, solid-state physics and nuclear physics. It uses the experimental techniques and apparatus of physics—photoelectric cells, electronics, spectrographs, image intensifiers—and it uses, and contributes to, the basic ideas and data of physics. There is, in fact, no essential difference between a modern university observatory and any other university science department.

I should like to give an illustration of what I have been saying. Astrophysicists were the first to investigate in detail the theory of radiative transfer, and the formation of spectrum absorption lines, and realized before anyone else the importance of collision broadening. All this is now a commonplace part of physics; but it was all started by astrophysicists. I feel that we cannot emphasize this point of view too strongly, and, to remind us that modern astronomy is a part of physics, I hope that we may see the name of the Oxford Observatory become 'Department of Astrophysics'.

Returning now to the main theme, I would say that until the late 1930's one could have expected to predict the future course of astronomy, say, for one decade at least, with some confidence. But he would have been a bold and imaginative astronomer who, in 1940, could have predicted successfully the state of affairs which now exists in 1962, only twenty-two years later. Now a spectrograph attached to a rocket can be used to investigate the solar spectrum in the short wave-length region which is absorbed by the Earth's atmosphere, and we have the exciting possibility of placing our telescope on a satellite well above the Earth's atmosphere. The solar system is being investigated with interplanetary probes, and its scale obtained by radar methods. Photographs have been taken of the other side of the Moon. Men have been put into orbit with their apparatus and brought safely back, although—perhaps heretically—I question the value of this tremendous achievement for astronomy. We have the fact of the astonishing development of radio-astronomy into a flourishing subject of its own. We have all the wonderful techniques of electronics which have been developed for the nuclear physicists and for rocket guidance systems, and we have fast computers which can solve problems a million times as complex as before the War. Is it any wonder that I apologize for my presumption in considering astronomical progress in the next twenty years. There has been as much progress in the past twenty years as there was in the preceding two thousand years.

---

* Substance of Prof. Blackwell's inaugural address, delivered on June 12. The full text will be published by the Clarendon Press, Oxford.

Faced with all these exciting achievements and possibilities, what kind of research should a university astronomy department do? I want to consider this problem now, but first I should like to suggest a basic principle. This is, that when a university department undertakes research, it must lead and not be content to fill in the trivial gaps in our knowledge. This is the crucial sentence in this article. But the university astronomer, wherever he is in Great Britain, is heavily penalized by the climate. My theme now is—how can we do significant research under such a disadvantage, and on a relatively small budget. I am going now to consider the various possibilities open to us, leaving until later the question of whether we are in a position to take advantage of these possibilities—a question which will bring us back to the relation between universities and their astronomy departments.

First, space research. For the academically minded there are three attractions of constructive space research, quite apart from any applications. The first attraction is that it enables us to investigate directly the environment of a space-vehicle. By space, here I mean interplanetary space, which hitherto has had to be investigated by somewhat indirect means from the surface of the Earth.

The second attraction of space research is that we are clear of the Earth's atmosphere, which wholly absorbs the radiation from celestial objects at wave-lengths shorter than 3000 Å, and partially in the infra-red at wave-lengths between 20μ and 1 mm. There is a rich field of investigation here which is undoubtedly worth while, although at enormous cost.

The third attraction is concerned with telescope performance. The advocates of space research say that instead of trying to do better by building Earth-bound telescopes larger than 200-in. diameter we should improve the performance of smaller telescopes by putting them into space vehicles.

Do not think that because there are these immense possibilities for astronomy in space research, observing from the ground is out of date and should be abandoned. Far from it—there is still plenty of opportunity for observing from the ground and plenty of scope for imaginative thinking. But I think that it would be foolish to neglect the possibilities of astronomical space research, and I am anxious to see Oxford participating in it in the years to come.

When we come to consider optical astronomy we are, in the light of our maxim, in an apparently difficult position. By optical astronomy I mean astronomical research made in those regions of the spectrum which are transmitted by the Earth's atmosphere, that is, in the range 3000 Å to the near infra-red, these observations being made from ground based observatories. In what follows I shall speak only of astrophysics, and not of astrometry, which is concerned with the measurement of the positions of the celestial bodies.

Britain is heavily handicapped by the climate. What should be done? I am convinced that if optical astronomy is to survive in the universities of Britain—and I emphasize that I am speaking now only of the universities—and to be an effective contribution to modern astronomy, it must, to a large extent, although not entirely, be carried on abroad. I direct attention to this qualification "not entirely", it is important. I do not intend that observing in Oxford should be curtailed. Clearly, it would be absurd to make an investigation in Oxford with the knowledge that the work can be done much better abroad. But there are some astrophysical problems which may be solved equally well in Oxford as abroad, particularly those which most usefully employ a photographic technique rather than a photoelectric technique. Because it is a two-dimensional detector, the photographic plate can gather information much more quickly than the photoelectric cell, which can only measure the flux of radiation through a specified area although the information that the plate gathers may not be so precise as that obtained by the photocell. The photographic technique is therefore a very suitable one for this rather poor climate, for it can gather a great deal of information during a few minutes of clear sky—information which may take some months to analyse.

On the other hand, I believe that the use of highly developed photoelectric techniques in a good climate abroad will lead to far-reaching advances, and I wish to refer to four ways in which I hope that this kind of work will be accomplished by Oxford astronomers.

The first way is by making an expedition to the best possible place for the solution of a particular problem. As an example, I refer to the 1961 Oxford/Cambridge expedition to the mountain site of Chacaltaya at an altitude of 17,100 ft. in the Bolivian Andes. The second way is to make an expedition to observe a particular astronomical event. An obvious example is an eclipse expedition, in which we may be interested in the solar corona. A third way involves making a long-term expedition to solve a particular problem. The physicist often thinks of the Sun as an immensely bright source which is surely radiating energy at a rate sufficient to satisfy the needs of any astrophysicist. On the face of it, this is true. The Oxford solar installation receives from the Sun 10^{21} photons per sec. But there are several aspects of solar physics for which even a flux of this amount is uncomfortably small, and these are the problems that we are beginning to think about at Oxford. In Oxford the investigations that we are thinking of might take centuries, but I am hoping that it may be possible to carry the work through at a station in the Mediterranean where the first part of it should be completed in a period of only five years.

The fourth way is to take our equipment to a large telescope abroad and I hope that in the future, in addition to working at Pretoria, we shall have the opportunity of accepting American hospitality at the National Observatory of Kitt Peak.

I have tried to show that astronomy is a fascinating, flourishing subject which is well worth enthusiastic support. But I think that it will be generally recognized that astronomy is a Cinderella among university subjects, and now I want to take the liberty of making a plea for more active support for it, and more appreciation of, and enthusiasm for, it in the universities. The astronomical world is as hard and as competitive as any other. I will emphasize again, that if a university undertakes research it should lead. Yet how can we progress, let along lead, in the face of the competition from overseas—a competition which originates in a genuine enthusiasm for the subject and an active desire to encourage its development by all possible means. In contrast to this attitude the astronomy departments in Britain are often regarded as expendable, and they are under constant pressure to make way for other larger and more powerful departments and, indeed, are thought unreasonable if they offer resistance These are hard words, but the astronomer's situation in the universities is no less hard Often he must work with no laboratory assistant or computing assistant, perhaps very little secretarial assistance, and only a small amount of workshop assistance Prof P M S Blackett has recently suggested that a research group of six scientists should ideally be supported by six technicians, together with one technician for each research student I suggest that an active astronomy group needs at least this number I have been at pains to say that modern astronomy is not a matter of gazing through a telescope, neither is it a routine matter of photographing stars or putting a photographic plate in a spectrograph, exposing on a stellar spectrum for an hour and then going home Apparatus, often quite complex, must be designed for each problem as it comes up, and for this kind of work a group of six scientists cannot easily manage with less than six technicians In practice, the number of technicians available to the astronomer is only a small fraction of this

It will be said that support must come from sources such as the Department of Scientific and Industrial Research and the Royal Society While this is true—and both these bodies have given generous support to optical astronomy—such support cannot easily provide the basic essentials which the astronomer requires as much as any other scientist, such as floor area and permanent laboratory assistants

A difficulty is that support depends to a large extent on the staff/student ratio, a ratio which is almost meaningless for a postgraduate astronomy department In fact, the Oxford Observatory does teach undergraduates, although it is a largely postgraduate department, and last year the Observatory staff gave more than seventy lectures and a large amount of demonstration time to undergraduates I have no doubt that our problems could be eased by making astronomy into a final honours subject But I am convinced that an astronomer should, like any other physicist, first receive a thorough basic training in physics and mathematics, and take up astronomy seriously only after he has completed his undergraduate course

There was a time when the study of astronomy was thought of as something very remote from everyday life This may have been true at one time, but it is certainly not true now I have not tried to justify astronomical research, but I have tried to show that astrophysics and its more wealthy brother space science, are fascinating, flourishing subjects with a great future I trust that we may have the opportunity to keep Oxford in the forefront of the astronomical world

PRESIDENT FOR 1963 OF THE BRITISH ASSOCIATION

SIR ERIC ASHBY

SIR ERIC ASHBY, Master of Clare College, Cambridge, has been elected president for 1963 of the British Association for the Advancement of Science He will deliver his presidential address at the next annual meeting in Aberdeen The British Association has made an excellent choice, for Sir Eric, who was born in 1904, is a man of many parts, whose services and wise counsel have been sought not only by scientists but also by educationists and politicians He was educated at the City of London School and eventually graduated with first-class honours in the University of London, where (at the Imperial College of Science and Technology) he read botany and was awarded the Forbes Medal in 1926

Sir Eric was then appointed a demonstrator and, after three years doing plant ecological field work in the Carnegie Desert Laboratory at Tucson, he returned to his College as lecturer In 1935 he was appointed reader in botany in the University of Bristol, then in 1938 transferred to the University of Sydney as professor In 1947 he returned to Britain to occupy the important Harrison chair in the University of Manchester There he remained for only three years, for by then Sir Eric's gifts of administration and his work for education had become so widely recognized that he was called to the vice-chancellorship of The Queen's University of Belfast, where he did much for the advancement and extension of that University After nine years, it must have proved a great loss to Belfast, but gain for Cambridge, when he (in 1959) was appointed Master of Clare College, Cambridge In the field of education, Sir Eric has done much, especially towards the integration of technology into higher education Moreover, he has contributed a great deal to extra-mural adult education, and rendered signal service to the establishment and advancement of the new universities in the emergent countries

The Second World War intercepted Sir Eric's academic work in Sydney, but that was to the benefit of Australia's war effort, for he became chairman of the Australian National Research Council, and conducted a survey for the Australian Prime Minister with the object of linking science with the war effort He was the first director of the Commonwealth Scientific Liaison Bureau and spent 1945–46 in the U S S R as counsellor and, for a time, as Chargé d'Affaires in the Australian Legation in Moscow As a result of this experience, he wrote a fascinating book, *Scientist in Russia* Among his other publications is *Technology and the Academics* which has been well received in the educational world As could be expected, Sir Eric has been the recipient of many honours (he was knighted in 1956), and is much sought after as counsellor and lecturer—he gave one of the first Granada–British Association Lectures in Guildhall, London, in 1959

With so many calls on his time, and the demands that his present academic position make on him, it is clear that Sir Eric is unable to carry out practical scientific research, though he is very active in the promotion and advancement of science This is a loss to botany His former botanical research may be said to fall into three categories (1) quantitative analysis of growth (working mainly on *Lemna*), (2) applications of statistical methods to ecology, (3) quantitative investigations of morphogenesis of leaves

NEWS and VIEWS

Henry Bryant Bigelow Gold Medal for Oceanography: Dr. J. C. Swallow

The Henry Bryant Bigelow Gold Medal was established last year in honour of Prof. Bigelow, one of the founders of the Woods Hole Oceanographic Institution (U.S.A.). This year, the Medal, which is accompanied by a cash prize of 2,500 dollars, has been awarded to Dr. J. C. Swallow of the (U.K.) National Institute of Oceanography.

The Swallow Float has become the principal tool for the study of deep-water circulations. The results of these investigations have revolutionized our conceptions of the character of the deep-water motions. Instead of the sluggish, widespread drift anticipated from continuity considerations, the deep layers seem to be moving briskly and not in accordance with any known process. Here, then, is a scientific fact that challenges the imagination. No one is more aware of this than Dr. Swallow. Since 1955, when the first trials of the float were made, there has not been a year in which he has not been at sea in pursuit of further understanding of the character of the deep-layer motions. In 1955 and 1956 he worked in the eastern basin of the North Atlantic aboard *Discovery II*. In the following year he brought *Discovery II* to join *Atlantis* in a co-operative study of a deep countercurrent off South Carolina. In 1957 he worked again in the eastern basin from the Norwegian research ship *Helland-Hansen*. Next, in 1958 he worked off Gibraltar. By 1960 he had concluded a year-long investigation of the deep motions to the south of the Gulf Stream. In 1961 he took part in the International Expedition to investigate the Faroe-Shetland overflow from the Norwegian Sea. During the past winter he joined the *Erika Dan* to measure the deep currents off Greenland and Labrador.

John Crossley Swallow was born at Newmill, Yorkshire, England, on October 11, 1923. He began his education at Holme Valley School. In 1940 he was awarded a scholarship at St. John's College, Cambridge. He read mathematics and physics for two years, after which he joined the Admiralty Signal Establishment, working mainly at the East Indies Station until 1947. He then returned to Cambridge, graduated with first-class honours in physics, and then joined the Department of Geodesy and Geophysics to work on techniques for seismic prospecting at sea. He applied these techniques extensively during a round-the-world voyage of H.M.S. *Challenger* during the period 1950–52 and continued this work in the North Atlantic during 1953. He was awarded the Cambridge Ph.D. degree in 1954 for a thesis on "Seismic Investigations at Sea". He joined the National Institute of Oceanography in 1954 where, one year later, he used his first neutrally buoyant float for tracking deep-water movements.

Scottish Reactor Centre: Dr. H. W. Wilson

Dr. Henry W. Wilson has been appointed director of the Scottish Research Reactor Centre. Dr. Wilson, who is at present a senior principal scientist and a group leader in the Nuclear Physics Division of the Atomic Weapons Research Establishment at Aldermaston, where he has served in the Atomic Energy Authority since 1955, is a graduate of the University of Glasgow and a former member of the staff of the Department of Natural Philosophy, in which he served as assistant, Research Fellow and lecturer prior to 1955. His experience includes a period of several years with Imperial Chemical Industries, and during 1951–52 he was a post-doctoral Fellow in the Radiation Laboratory in the University of California, Berkeley. Dr. Wilson is a leading authority in the field of radiations from radioactive substances, and the research work of his mass spectrometry group has gained international recognition. The Reactor Centre, which is financed by a grant from the Department of Scientific and Industrial Research (see *Nature*, **194**, 338; 1962), is being set up in the grounds of the National Engineering Laboratory at East Kilbride. The Centre is the responsibility of a consortium of the four Scottish universities, the Royal College of Science and Technology, and the Queen's University of Belfast, and will be conducted under the general supervision of a committee of the principals of the participating institutions.

Geology at Hull

Dr. D. T. Donovan

Dr. D. T. Donovan, at present reader in palæontology in the University of Bristol, has been appointed as from next October to the newly founded chair of geology in the University of Hull. Shortly after graduating in 1942, Dr. Donovan was with the British forces in Palestine until he returned to the University of Bristol in 1946 to continue his interrupted researches. He joined the staff of the Department of Geology as an assistant lecturer a year later, was promoted to lecturer in 1950, and in 1962 was appointed reader in palæontology. He was awarded the degrees of Ph.D. in 1951 and D.Sc. in 1960.

Nurtured on the classical sections and exposures of the Jurassic rocks of the West Country, where he gained much from his association with Arkell and, to a lesser extent, with Spath, Dr. Donovan will doubtless direct his attention to the equally famous Mesozoic rocks of Yorkshire and adjacent counties to the south. Here, much has been accomplished and many of the problems of Jurassic stratigraphy and palæontology solved, but there still remains a rich field for research on the sedimentary environments and processes which controlled deposition. His extensive knowledge of Jurassic rocks and fossils abroad, from East Greenland to Italy, will also help to fit British Jurassic geology into a wider palæogeographical setting. Latterly, Dr. Donovan has turned his attention to marine geology and has developed the application of oblique asdic to geological mapping, as witness his recent contribution with Mr. A. H. Stride to the geology of the sea-bed off Dorset. Experience gained in the Bristol and English Channels will prove a useful introduction to the determination of the off-shore geology of Yorkshire, in particular the extension of the Jurassic rocks, and it is hoped that the obvious maritime interests of Hull and the Humber will give him the help he will need of ship's time.

Soil Science in Western Australia

Prof J Quirk

Dr James Quirk has been appointed to the newly created chair of soil science and head of the Department of Soil Science and Plant Nutrition within the Institute of Agriculture of the University of Western Australia This is the first full chair in soil science and department of this name within any Australian university Dr Quirk is aged thirty-seven and expects to take up duties early in 1963 He graduated from the University of Sydney in 1947 with honours in agricultural chemistry and obtained his Ph D in soil physics from the University of London in 1952 while working with the late Dr R K Schofield, head of the Soil Physics Department of the Rothamsted Agricultural Experimental Station For the following four years he worked with the Commonwealth Scientific and Industrial Research Organization Division of Soils in Adelaide and was appointed to his present position as reader in soil science at the Waite Agricultural Research Institute of the University of Adelaide in 1956 Dr Quirk has travelled and lectured extensively in Europe and the United States and has an impressive research record in soil physics He has specialized particularly in soil structure problems, the clay–water systems of soils and the relation of water stress to nutrient uptake by crop plants

Magnanimity

Sir Charles P Snow's rectorial address on "Magnanimity" to the University of St Andrews on April 13 has been issued as a pamphlet together with the laureation address of Prof A J McDonald in presenting Sir Charles, Prof P M S Blackett and Mikhail A Sholoklov for honorary degrees on that occasion (Pp 23 St Andrews, Fife Students' Representative Council, The University, 1962 2*s*) Sir Charles thought that Britain was in danger of losing this major virtue, and that while her society was in some respects more tolerant than the American, it was far and away less magnanimous Integrity had taken on a new meaning and no longer bore the quality of oneness encountered in characters like Einstein, Rutherford or Hardy, moral was coming to mean censorious, and there was a real danger of people forgetting what it is like to be generous to one another. This was happening at a time when the major social task—that of meeting the needs of the under-developed countries—demanded every scrap of courage and magnanimity that could be found The roots of magnanimity were complicated they included love, compassion, charity or brotherhood—whatever one called the 'binding glue' of society—that sense of reality which was also part of humour and a kind of vanity Nor did Sir Charles think we would show social or political virtue if we failed to make the most of ourselves as individuals in our human relations

The National Council for Technological Awards

The report of the National Council for Technological Awards for the period April 1961–March 1962 records 6,201 students as now following courses recognized by the Council and 1,092 diplomas have already been awarded, 620 being conferred during the period under review (Pp 51 London The National Council for Technological Awards, 1962) Of this latter total, 207 were in electrical and 158 in mechanical engineering, 70 in applied physics, 49 in production engineering and 47 in applied chemistry and chemical technology A list of 111 courses at 28 colleges which are now recognized by the Council is included in the report, and appendixes include extracts from written evidence submitted to the Robbins Committee on Higher Education During the period, 17 applications for registration as candidates for membership were received by the College of Technologists, making a total of 51 since the College, in November 1959, issued its memorandum outlining the method of application, and of these 40 have been accepted and a further 4 are under consideration

Political and Economic Planning

The annual report 1961–62 of Political and Economic Planning covers the year ended March 31, 1962, in which the sales of reports were still at the second highest figure in PEP's history, although below the level of 1960–61 The six projects in the present research programme may be grouped under two broad themes (1) change and adaptation to change in economic and social policy, including Britain and the European Common Market, attitudes in British industry, Trade Unions in a changing society, and education and training programmes for developing countries, (2) social policy and family life, including community mental health services and prisoners' families The first project was started in September 1958 and will continue for a further three years from November 1961; a report on Atlantic Tariff and Trade is in the press and an examination of the consequences for industry of setting up the Common Market has commenced Three principal inquiries are being made into community mental health services, covering the collection of data on turnover and interchange of mental patients, on interview survey of psychiatric patients living in the community and of members of their families, and a survey of social work in mental health The three-year project on prisoners and their families is in two main parts an interview sample on a national basis, and a more intensive study of up to a hundred prisoners' families in the London area The study of education and training programmes for developing areas now envisaged is in four parts This comprises compilation of an inventory and analysis of training facilities in the United Kingdom for overseas students wishing to qualify as technicians, technologists, scientists or professional workers, an examination of the types of social facilities available to students, a review of problems which may deter members of the staff of United Kingdom teaching institutions from taking up overseas posts, and a study on the spot in a selected developing area of the provisions for higher technical and scientific training in relation to the level of development of the area and to existing attitudes to change

International Antarctic Analysis Centre

The southern hemisphere is an empty waste, meteorologically speaking The proportion of land mass is comparatively small while the water areas are infrequently traversed by ships The lack of data greatly restricts research Yet the geography of this hemisphere closely approximates the ideal general circulation models which are studied in the laboratory, on the charting bench and by the theoreticians The International Antarctic Analysis Centre was established in Melbourne by the Commonwealth Bureau of Meteorology in 1959 following on a recommendation of the Special Committee for Antarctic Research at its Moscow meeting in 1958. It has now been operating for three years and is staffed by five professional meteorologists from Australia, Argentina, France and the United States, constituting a truly international team The programme of work undertakes to analyse circumpolar 700, 500 and 300 mb constant pressure charts over the area south of 60° S at 00 and 12 G M T daily At 00 G M T the analyses are extended northwards to about 30° S The charts are later re-analysed after the entry of new synoptic data The final product is microfilmed. A library of data is thus being built for future research workers engaged in studies of the meteorology of the southern hemisphere and of the global atmospheric circulation The hope has been expressed that the International Antarctic Analysis Centre may itself soon partake in such research

The Pengelly Cave Research Centre

The Pengelly Cave Research Centre was founded on March 31, 1962, at a joint meeting of the Society for the Promotion of Nature Reserves, the Devon Naturalists' Trust and the Devon Spelæological Society (*News for Naturalists,* 4, No 1, July 1962) The headquarters of this new Centre, which has been named after William Pengelly, the pioneer nineteenth-century excavator of Kent's Cavern, are at Higher Kiln Quarry, Buckfastleigh, purchased in October, 1961, by the Society for the Promotion of Nature Reserves, and is to be developed for the furtherance of cave research in Britain The site is already well known to cavers and naturalists as containing the entrances to Reed's and Joint Mitnor Caves The acquisition of Higher Kiln Quarry by a scientific organization provides an opportunity, for the first time, of developing a much-needed cave research and demonstration centre in Britain The site is exceptionally well suited for this purpose, for not only is it easily accessible, but it also contains a variety of features, usually available only over a distance of several miles

At the present time Britain lags behind countries such as France (which already has a well-equipped underground laboratory at Moulis, in the Pyrenees), Belgium, Yugoslavia, the United States and Cuba in the facilities for cavern research which it has to offer to spelæologists There is no means whereby the naturalist or student who is not a spelæologist can obtain first-hand experience of the natural history of caves. Moreover, the great increase in the popularity of caving as a sport in Great Britain presents a serious threat to the preservation of much of scientific importance that the British caves contain unless steps are taken to educate cavers One of the objects of the Centre will be the development of conservation-mindedness

National Parks of Canada

Two of Canada's National Parks are discussed in booklets issued by the Geological Survey of Canada (Canada Department of Mines and Technical Surveys Geological Survey of Canada *Miscellaneous Report No 4 Yoho National Park—the Mountains, the Rocks, the Scenery* Pp vi+107 1 dollar. No 5. *Cape Breton Highlands National Park—where the Mountains Meet the Sea* By David M Baird. Pp vi+65 75 cents Ottawa Director, Geological Survey of Canada, 1962) Both have been prepared by David B Baird, who has taken some outstanding photographs to add to the attraction of the booklets The text has been prepared with such commendable skill that either booklet would serve as an introduction to petrology as well as a helpful guide to some of Canada's outstanding scenery

Biology and Human Affairs

A novel approach to food production and storage in plants is described in an outstanding editorial comment in *Biology and Human Affairs* (27, No 3, Summer 1962) Among the other articles is one on crop plants by N W Simmonds, an account of his work on the ecology of ants by J W Siddorn, the place of mathematics in biology by M J R Heeley, and various aspects of human learning and understanding by Dr E C Poulton The journal is published by the British Social Biology Council, 69 Eccleston Square, London, S W 1

Space Science Reviews

The first issue of a new international quarterly journal *Space Science Reviews* recently appeared (1, No 1, June, 1962. Edited by C de Jager Pp 154 Published quarterly (Dordrecht D Reidel Publishing Company, 1962) Subscription price 150 florins, 42 dollars per volume of four issues) The editor-in-chief, C de Jager, of the University of Utrecht, explains in the introduction that the journal will not include original research papers, but will consist of invited review articles on particular aspects of space science and technology. Each issue will run to about 180 pages, containing between 5 and 8 contributions Space research, as it expands, is covering an ever-broadening area of science, and the journal should meet the widely acknowledged need for authoritative and up-to-date reviews The first issue has 6 excellent contributions First, H Wexler discusses the results obtained from the *Tiros* weather-satellites Then follow four articles on strong solar disturbances and their effects H Carmichael describes the high-energy solar-particle events of 1959–61, E N Parker and T Gold (in separate articles) discuss the mechanism of geomagnetic storms; D C. Rose and S. Ziauddin consider the polar cap absorption effect Finally, T M Donahue reviews the possible sources of the Lyman-α radiation observed in the night sky

Radioactivity in Drinking Water

Investigations by the Government Chemist show there was no appreciable increase or decrease in amounts of radiostrontium and radiocæsium in United Kingdom drinking water during 1961 (Ministry of Housing and Local Government; Scottish Development Department, Ministry of Health and Local Government, Northern Ireland *Radiostrontium and Radiocaesium in Drinking Water in the United Kingdom—1961 Results* Pp 19 London. H M S O, 1962 1*s* 6*d* net) The investigations do not cover samples taken in 1962, but the evidence so far available indicates that the Russian nuclear tests in the autumn of 1961 are unlikely to have caused higher levels of strontium-90 in drinking water this year than during 1959 In 1961 drinking water contributed less than 5 per cent of the total amount of strontium-90 in the average diet, the amount of cæsium-137 in drinking water was about half the quantity of strontium-90 Details of these and other radioactive substances in diet are given in periodic reports by the Agricultural Research Council's Radiobiological Laboratory, the most recent of which was published in May, 1962 This report on drinking water is the fourth on this subject in the Government's monitoring programme, and states that well water remains virtually free from radioactivity Impounded waters generally have higher levels than river water

U S Committee on Extension to the Standard Atmosphere

THE co-chairmen of the above U S national effort, described in *Nature* of July 14, p 133, are Mr Maurice Dubin, National Aeronautics and Space Administration, Mr Norman Sissenwine, Geophysics Research Directorate, Air Force Cambridge Research Laboratories, and Dr Harry Wexler, U S Weather Bureau

University and College News

Birmingham

THE College of Advanced Technology, Birmingham, was transferred to an independent Board of Governors as from April 1, 1962, and the latest report of the principal, Dr P F R Venables, covers the period September 1960–March 1962 (Pp 40 Birmingham College of Advanced Technology, 1962) During this period 220 students were admitted to the Associateship at the Presentation Ceremony in 1961. and 264 Associates were admitted in March 1962 Grants for research were received in the form of the Wilmot Breeden and the Lucas Research Fellowships and a Ministry of Aviation Research Fellowship. A Research Fellow has been appointed in the Department of Industrial Administration for a research project to investigate end-on arrangements in the development of sandwich courses, which was established with a grant of £6,700 from the Nuffield Foundation One senior Research Fellow and two research assistants were appointed to a research unit established with a grant of £28,580 from the Department of Scientific and Industrial Research to investigate social factors affecting relations and individual performance in factories Of 5,359 students in the session 1960–61, 1,264 were full time, 2,072 in part-time day courses and 2,023 in evening courses only, for the past session 1961–62 the corresponding figures were 1,386, 1,605 and 1,991 Enrolments in sandwich courses totalled 838, 282 being in mechanical and production engineering and 250 in electrical engineering In 1961–62 the total increased to 956

Cambridge

THE following election to fellowships (Title *A*) at Churchill College have been announced Dr J D C McConnell, of Fitzwilliam House (University lecturer in mineralogy, College lecturer in mineralogy), F H McClintock, of Trinity College (assistant director of research in criminology, College lecturer and director of studies in law), A A Sinclair (College lecturer and director of studies in history)

Oxford

PROF. R PEIERLS, professor of mathematical physics in the University of Birmingham, has been appointed to the Wykeham professorship in physics with effect from October 1 Dr V Zussman has been elected to the readership in mineralogy and will take up his appointment in the academic year 1962–63 The following appointments to lectureships have been announced Dr D A Edwards, A W Ingleton, J D Murray (mathematics), F O MacCallum (virology), D J Roaf (theoretical physics), Dr W E Parry (physics)

Announcements

AIR COMMODORE B Samson, has been appointed director, Aircraft Mechanical Engineering Equipment Research and Development, with effect from August 13 Previously he was senior technical staff officer with Near East Airforce

A SYMPOSIUM on "Fungi and their Metabolites" will be held by the Plant Phenolics Group and the British Mycological Society at the School of Pharmacy, Brunswick Square, London, W C 1 during October 1–2 Further information can be obtained from Dr J G Manners, Department of Botany, the University, Southampton

THE Institute of Biology is organizing a symposium on "Colour and Life" to be held at the Harkness Hall, Birkbeck College, during September 20–21 The symposium is open to members and non-members of the Institute, for the latter, however, there will be a fee of 21*s* Further information can be obtained from the General Secretary, Institute of Biology, 41 Queen's Gate, London, S W 7

A SYMPOSIUM, organized by the Nutrition Society, will be held on "Assessment of Nutritional Status in Man" at the Lecture Theatre, Chemistry Building, Meston Walk, Old Aberdeen, on September 29 Further information can be obtained from the honorary secretary of the Scottish Group of the Nutrition Society, Dr D G Armstrong, the Hannah Dairy Research Institute, Ayr, Scotland

A CONFERENCE of European comparative endocrinologists will be held in London at the Rooms of the Zoological Society during September 20–22 Further information can be obtained from the convenors, Prof H Heller, Department of Pharmacology and Practical Pharmacy, the University, Bristol 8, and Prof E J W Barrington, Department of Zoology, the University, Nottingham.

THE Third International Machine Tool Design and Research Conference will be held at the Department of Mechanical Engineering, University of Birmingham, during September 24–28 Further information can be obtained from the Organizing Secretary of the Third International Machine Tool Design and Research Conference Department of Mechanical Engineering, the University, Edgbaston, Birmingham 15

THE Faraday Society is organizing a general discussion on "High Resolution Nuclear Magnetic Resonance" at the University of Oxford during September 17–19 The discussion will be divided into (1) nuclear magnetic resonance in diamagnetic materials, (2) nuclear magnetic resonance in paramagnetic materials, (3) applications to the determination of molecular structure; (4) applications to the study of kinetic processes Further information can be obtained from the Faraday Society, 6 Gray's Inn Square, London, W C 1

THOMAS GRAHAM AND THE DEFINITION OF COLLOIDS

By Prof S G MOKRUSHIN

Urals Polytechnical Institute, Sverdlovsk, U S S R

At present we have two definitions of colloids The 'founder of colloid chemistry', Thomas Graham[1], one hundred years ago, defined the colloids as substances of complicated chemical nature with very high molecular weight and a specific structure of molecules Owing to this fact the molecules of colloids possess the properties different from those of crystalline bodies or crystalloids But Graham emphasized that the process of solution of colloids, that is, the formation of solutions and the phenomena which accompany them, differ from those of crystalloids only in degree The solution of colloids is very slow and the change of temperature is barely perceptible Graham defined the colloidal state as a dynamical state of matter which may change into a crystalloidal statical condition The colloidal state of matter possesses *energia*, and Graham suggested that the phenomena associated with life in those bodies which consisted almost wholly of colloids is due to that *energia*

The world of colloids is particularly the world of organic high-molecular substances, however, Graham showed that inorganic substances composed of molecules of high molecular weight and complicated structure can be also obtained in colloidal state The solutions of colloids are real solutions and they obey the laws of physical chemistry and thermodynamics According to Graham the colloidal state of substances is determined by the high molecular weight

In his papers Graham does not mention the investigations of Faraday[2] on the finest suspensions of metallic gold, nor the works of Selmi[3] on pseudo-solutions The finest suspensions of gold and pseudo-solutions of Selmi are not real solutions but micro-heterogeneous systems Graham, in agreement with his conception of colloids, never assumed that the finest suspensions of gold, silver chloride, sulphur and other similar systems are colloidal solutions

But about half a century after the establishment of colloid chemistry by Graham, a new definition of colloids was proposed by Freundlich, Wo Ostwald and Weimarn[4] which did not conform with that given by Th Graham These scientists proposed to call any substance which is in the dispersed state 'colloidal' The molecular weight of the dispersed substances had no relation to the colloidal state by that definition The finest suspensions or emulsions of dispersed substances in a medium were colloidal solutions according to them

Graham would not have considered the solutions of Freundlich, Ostwald and Weimarn as real solutions but as microheterogeneous (dispersed) systems This second definition of colloids was accepted by most scientists and the finest suspension of gold was considered as a typical colloid[5]

Meanwhile, it is necessary to recall that Graham chose gelatin as the prototype of colloid[6]

The difference between the points of views of Graham and the later three authors as to the question of what the typical colloid is, is evident

Those who supported the dispersoid conception as an explanation of the behaviour of Graham's colloids (high-molecular substances) in solutions, ascribed much greater hydration to them than could be proved by experiment[7] Since Staudinger[8] introduced the conception of 'macromolecule', some scientists[9], fortunately only very few, proposed not to consider the colloids of Graham as colloids, but to refer to them only as high-polymers because these substances made real solutions but by no means microheterogeneous (dispersed) systems

However, it will be noted again that Graham always considered the colloidal solutions as real solutions and never as the pseudo-solutions or microheterogeneous systems But both these definitions of colloids may be reconciled if we assume, with Perrin[10], the definition of 'gigantic physical molecule', which in its physical and thermodynamic behaviour has no distinction from the behaviour of chemical molecules Therefore we may regard the finest suspensions of those particles which show Brownian movement and obey the laws of kinetic theory of heat as real solutions Einstein[11], Perrin[10], Svedberg[12] and Smoluchowski[13] proved this conception to be true by theoretical and experimental investigations

Thus we may conclude that modern colloid chemistry is the physical chemistry of gigantic physical and chemical molecules

UNIVERSITY ENTRANCE REQUIREMENTS IN ENGLAND AND WALES

In March 1960 the Committee of Vice-Chancellors and Principals set up a sub-committee, including a substantial proportion of university teachers, to report on university entrance requirements, and the preliminary report of this sub-committee in March 1961 satisfied the Vice-Chancellors and Principals that the time was opportune for a careful reconsideration of entrance requirements by the universities When the draft report was circulated as a confidential document to the universities for comment, there was an almost uniformly favourable response to the proposal for some alignment in form and approximation in substance of present entrance requirements The Committee of Vice-Chancellors and Principals has accordingly asked universities forthwith to restate their present requirements in a common form, and at the same time, where possible, to bring them closer into line when they differed in substance

This restatement is now being carried out, with a view of publication in a combined volume before the end of this year A second main proposal of the draft report*, a new pattern of entrance requirements, was put forward as an educational reform, and after careful examination, Cambridge, London and Reading expressed opposition in principle. Oxford has not yet given any opinion, but the remaining universities approved or welcomed the idea of the proposal, and comments offered were directed to modifications of detail The Committee of Vice-Chancellors and Principals judged, therefore, that there was sufficient university support to justify the wider discussion of the proposal, and its publication was authorized in this report after redrafting to meet most of the points raised in the detailed comments

The report opens with a brief historical review of the development of university entrance requirements in England and Wales in their present form over the past sixty years or so, and this is followed by an analysis of the present difficulties arising from variations and ambiguities in the method of statement of entrance requirements by universities, variations in the entrance requirements themselves, whether in subjects named or in the numbers of subjects in which passes are required, or from the weakness of the general pattern of entrance requirements

The first proposal, already being implemented, is that all universities in England and Wales should publish their examination requirements for entry on first-degree courses in a common form, using standard terms. In this common form the terms 'matriculation requirement' and 'minimum entrance requirement' are replaced by the term 'general requirement', to denote the group of required passes at both levels in the General Certificate of Education, examination equivalent to what is now demanded for Matriculation Similarly, the term 'course requirement' is proposed in place of 'faculty requirement' and 'department requirement' to denote the group of required passes at both levels in the General Certificate of Education examination equivalent to what is now asked for entry into specified faculties or departments, and this Course requirement should be stated in terms of numbers and names of subjects in which 'normally' a candidate should have passed, to hope to be academically acceptable to the department or university concerned As already indicated, the proposal contemplates that each university will print and publish its entrance requirements for first-degree courses in single joint annual volume

The second proposal is more far-reaching and radical, and the Committee believes that adoption of this proposal would not only automatically remove some of the formidable difficulties for candidates which now arise from the interlocking of the minimum entrance requirements and the faculty and department requirements, in terms of General Certificate of Education subjects at both levels, but by placing more weight than hitherto on general studies than special studies in the sixth form, could permit an educational improvement of considerable benefit both to universities and to schools The present balance between general and special studies is the result of piecemeal adjustments made over a long period as conditions in the schools and universities have slowly changed and as the structure of public examinations has been altered Tacitly abandoning their former requirement of a broad intellectual training alone as a condition of entry, the universities have substituted for it a primary demand for competence in subjects of special study, and evidence of general education has become a secondary requirement, the test for which is made at the beginning of the sixth-form course The essential new feature of the proposed new pattern is that it recognizes the importance of general studies in the sixth form by making them examinable, just as are the subjects of special study

The essence of the proposed pattern is to replace the Ordinary Level papers at the end of the fifth-form year by new papers in the second sixth-form year as the university test of a candidate's general education, although it is assumed that most boys and girls will continue to take and to pass the same range of Ordinary Level subjects as they now commonly do before entering the sixth form Under it the entrance requirements would be in two parts, a general and a course requirement, each of which must be fulfilled The latter would be confined to passes in the General Certificate of Education examination, and including at least two Advanced Level passes. The General requirement would consist of required passes in the following new papers, taken not earlier than January in the candidate's second year in the sixth form a paper in the use of English; a general paper, and a paper in the use of foreign language The first would be designed to encourage the serious study of the use of English in the sixth form, the second should be set on the assumption that at an earlier stage candidates will have passed at Ordinary Level in either mathematics or a science subject and also in two or three of the usual arts subjects

The proposals leave room for variation between universities both in the general requirement and in course requirements, and if the new pattern is adopted a transitional period will be necessary during which universities will allow candidates to fulfil requirements either of the existing pattern or the new The timing suggested for the examination for this new general requirement, however, would reinforce the efforts already being made by the Secondary School Examinations Council and other bodies to reduce the excessive weight of Advanced Level syllabuses Moreover, through the firm claim established on a reasonable proportion of sixth-form time for general studies it should afford a wholesome check to excessive specialization and influence those who prescribe syllabuses and the examiners who deploy them to do so in a realistic manner

The note of sanity and realism in these proposals should be widely welcomed in the world of science While they will do nothing to reduce the competition for university places, they should offer a fair prospect of checking premature specialization than earlier measures that have been tried in individual universities, and, particularly by fostering the study of English in the sixth form, assist to remove one weakness in the scientist and technologist that has been a wide source of complaint and criticism The fact that most universities are already known to agree with the proposals is promising, but it is to be hoped that those who have expressed opposition in principle will not fail to come into line Simultaneously, with the re-examination of syllabus in the science subjects themselves, it offers an opportunity of improvement that is unlikely to recur but which if seized with vision and determination could transform the whole training of the science graduate Any university should hesitate before raising obstacles or imposing requirements which could cause the opportunity to be missed.

---

THE MELLON INSTITUTE

THE annual report of the Mellon Institute for the year ended February 28, 1962*, records expenditure of 5 9 million dollars on independent and sponsored research At the end of the year the Institute's staff was 561, and 362 professional and technical members were reporting on some 100 investigations A list of publications of members during 1961 other than patents or periodicals or reports that do not appear in the open literature is included Eighteen appointments at the level of Fellow were made during the year, half of whom joined Independent and half Sponsored Research The Research Services of the Institute in its Instruments Section placed emphasis on systems which completely programme experimental procedures and increase the amount and accuracy of the information recorded An instrument was constructed for the automatic recording of additives during redox measurements, a low-temperature (40° K to ambient) controller designed and built for the magnetic susceptibility programme and a circuit design of the instrument and servo system completed for a 'hot hardness tester' In the Physicochemical Section the study of adsorbed organic molecules on catalysis by infra-red spectroscopy was extended, and a study initiated to find a correlation, if any, between the presence of trace elements and the occurrence of cataracts of the eye The Microbiology and Microscopy Section completed a study of microbiological sludge inhibitors for jet fuels

Under independent research, the report records continuing work on the detailed characteristics and distribution of plasma and red-cell hydrolytic enzymes, with special emphasis on the enzymes of the circulating blood which attack the hypotensive polypeptides, bradykinin and kallidin Investigations are being continued on the interrelation between metabolites of *p*-aminobenzoic acid and aniline hydroxylation by resting cells of acid-fast bacteria, and completion of an electron microscopical study of ribonucleic acid from tobacco mosaic virus is reported. In organic chemistry, besides investigations of the acylamidines, the rotational isomerism in mono- and di-alkylpropenes of the types $R\,CH_2\,CH=CH_2$ and $R_2CH.CH=CH_2$ has been investigated by nuclear magnetic resonance spectroscopy, and a five-step synthesis developed of 1 . 2 3-triphenyl-4 5-benzpentalene Efforts are being directed to develop general routes for the synthesis of branched polymers of the star type and of the comb type, and the stereochemical structures of polymers prepared by free-radical polymerization of methyl methacrylate have been computed from high-resolution nuclear magnetic resonance spectra measured at room temperature in chloroform solutions Preliminary experiments have been made on the effects of heterogeneity in chain length, in chain branching, and of diluent on the relation between molecular weight and flow of high polymers in bulk or in concentrated solution The basic studies in co-ordination chemistry led to the discovery of several unusual complex compounds, including a univalent iridium compound which reacts at normal conditions with a number of molecules commonly regarded as relatively inert In physical chemistry, low-frequency infra-red spectroscopy and the vibrational spectra of inorganic substances have been particularly fruitful fields, and in radiation chemistry the electron-spin-resonance studies of radicals have been extended to a variety of hydrocarbons Photochemical investigations largely focused on such systems as phosgene–olefine mixtures, 1 · 2-dichloroethylene and ethyl and vinyl iodides Work continued on a mathematical theory of fluid behaviour within which many fluid–flow problems can be solved, and attempts are being made to find exact solutions for the steady-state Schrödinger equation for systems of two or more electrons in the potential field existing in an arbitrary molecular framework

In metal physics, low-temperature calorimetry studies are in progress to obtain more reliable data for the copper–zinc and related binary systems The study of stacking-fault probabilities in noble metal alloys has been extended to the silver–cadmium system, where a linear relation between the faulting probability and composition has been observed over compositions containing 0–30 atomic percentage of cadmium

A group of investigations concerned with public welfare range from air purification, the processes involved in the deterioration of artists' materials, toxicity of new organic chemicals, industrial hygiene, mine acid control, steel protection and water resources Notes are also included on progress in projects concerned with the development of solid catalysts from bone products for organic reactions, ceramic chemicals, aspects of forming and treating structural clay products and performance of plant scale equipment, starch-based chemicals as textile warp sizes, the performance of industrial fabrics from felt, ferrous alloys, a hydrogenation method for determining low concentrations of organic sulphur in natural gas, the chemistry of petroleum genesis; the fundamental nature of the activity of catalysts; studies of metal surfaces in hydrogenation, silicones; the synthesis of phosphonitriles; and the degree of susceptibility of selected high-strength case steels for rocket motors and other alloys to stress-corrosion cracking

HYDROLOGY OF RIVER FLOOD-PLAINS

By R C WARD

Department of Geography, University of Hull

TO the agriculturist, the flood-plains of rivers have, for a long time, been some of the most interesting hydrological areas of a drainage basin In past centuries these low-lying valley bottom lands were used as flood meadows which were inundated each year In this way the topsoil was enriched by the deposition of silt from the flood waters and a reserve of soil moisture was built up to assist grass growth in subsequent periods of deficiency in rainfall To-day, the old sluices have been replaced by the aluminium pipes and sprinklers of overhead irrigation which can often be carried out most economically in valley meadows owing to the proximity of a readily available source of water in the nearby stream or river As a result of the particular hydrological conditions present in a flood-plain, however, this often abundant source of water can be potentially dangerous The aim of this article is to examine some of these hydrological conditions and to assess their relevance to irrigation practices

The flood-plain in relation to the drainage basin Fig 1 shows the relationship of a flood-plain to the hydrology of a hypothetical drainage basin It is at once evident that there is a direct contrast between the zones of ground-water present in the flood-plain and those present in the valley flanks and terraces In the latter, four zones are represented, that is, the soil zone, the intermediate zone, the capillary fringe, and the zone of saturation below the water-table

The soil zone, limited as its name implies by the depth of soil above the bed rock, contains water which has infiltrated through the surface and which is held by adhesion to the surfaces of soil particles and in interstices between grains and rock fragments Water moves out of the soil zone, either by means of evaporation and transpiration into the atmosphere or when the soil is holding all the water it can against the force of gravity (that is, when it has reached field capacity), by means of downward percolation towards the water-table Immediately above the saturated zone is the capillary fringe, where water is held against the force of gravity by means of capillary action, and between this and the soil zone is the intermediate belt, where water is held by adhesion to particle surfaces Finally, below the water-table is the zone of saturation, where all the cracks and interstices are filled by ground-water

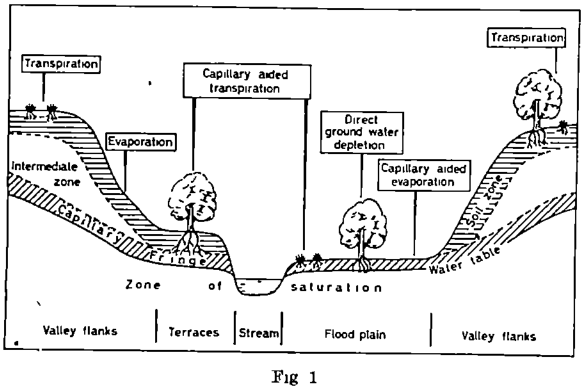

Fig 1

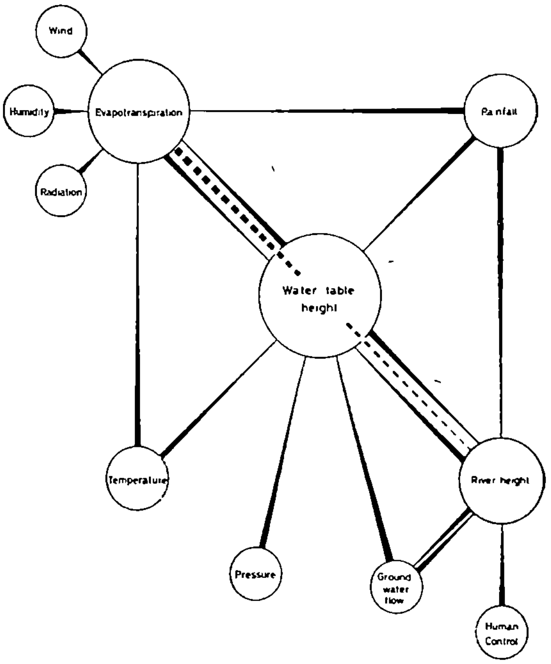

Fig 2

A different situation, however, exists in the flood-plain areas of the drainage basin, where the capillary fringe may extend either into the soil zone or even to the ground-surface itself, depending on the distance between the water-table and the ground-surface and on the height of the capillary fringe Since the water-table is often less than 5 ft below the ground-surface, except in the late summer, it is apparent that, for the greater part of the year, the vegetation of the flood-plain is able to draw on much larger supplies of soil moisture than is the vegetation on the valley flanks and terraces Thus, relatively speaking, losses of water by evapotranspiration will tend to be far higher from the flood-plain than from other areas of the drainage basin Penman[1] emphasized this duality of catchment areas, and pointed out the contrast between the flood-plain, where the high water-table enables the ground-water to contribute to evapotranspiration losses and the higher land, where the soil moisture deficit increases through the summer and ends only when rainfall eliminates it " . from the top downwards"

Although, however, this duality can be recognized in theory, it is virtually impossible to assess quantitatively the individual contribution of either the flood-plain or the higher land to the water-balance of the catchment area as a whole This is due to the difficulty of estimating not only the losses of water from the higher areas, where soil moisture is is not often maintained at a level sufficient to enable evapotranspiration to take place at the potential rate but also the considerable quantities of water which move from the valley flanks to the flood-plain and down the valley through the flood-plain deposits.

Water relationships of the flood-plain. Despite the difficulties of determining exactly the hydrological relationship of the valley bottoms to the remainder of the drainage basin, it is, nevertheless, possible to outline in greater detail the water relationships of the flood-plain areas.

Fig. 2 shows diagrammatically the relationships and interactions between the various factors concerned in the hydrology of a flood-plain. The height of the water-table has been placed in the centre of the 'web' because, alone, it is capable of reflecting the balance of forces exerted by all the other factors. Fluctuations in the height of the water-table are mostly caused by rainfall, evapotranspiration and variations in river-level.

Rainfall, in fact, always exerts some influence on the height of the water-table in any part of a drainage basin since ground-water itself is ultimately derived from precipitation. Its direct effects are of most relevance to the present discussion, however, and can be most striking. For example, if the moisture content of a heavy soil is already high, a rainfall of 1 in. can easily result in a rise of the water-table by some 6–7 in. where, as in a flood-plain, the water-table is already close to the ground-surface. The main influence of evapotranspiration is normally on the moisture content of the soil but again, owing to the height of the water-table in a flood-plain, water lost by evapotranspiration is often extracted directly from the ground-water, resulting in a fall in the level of the water-table. The influence of a river on the fluctuations of the water-table in an adjacent flood-plain will largely depend on the composition of the flood-plain deposits. If these are coarse and gravelly, ground-water movement between the river and the flood-plain will be rapid and, consequently, variations in river-level will tend to be reflected in similar movements of the water-table. On the other hand, if the flood-plain deposits are fine and silty, variations in the river-level are not likely to be transmitted to the adjacent water-table except in a very modified form.

Apart from these major influences exerted by rainfall, evapotranspiration, and river level, water-table height can also be affected by other factors. For example, a rise in barometric pressure may, especially if the soil moisture content is high, cause a decline in water-table height. Furthermore, since the water-table is the upper surface of the zone of saturation, it follows that variations in ground-water flow will also be reflected in the height of the water-table.

However, changes in water-table height can themselves exert a considerable influence both on the amount of water lost by evapotranspiration since the smaller the distance between the ground-surface and the water-table the greater is the likelihood of ground-water extraction by plant roots and also on river-height, because when the water-table is higher than the river, ground-water flow into the river will tend to occur.

Finally, Fig. 2 indicates that both evapotranspiration and the height of the river are influenced by other factors. The former, for example, is governed principally by climatic factors such as temperature, solar radiation, humidity, wind-speed and rainfall, while variations in river-level are influenced by rainfall, by the amount of evaporation which takes place from the water surface, by ground-water flow through the flood-plain and by human control such as locks, weirs and sluices.

The relationship of a flood-plain to the complete drainage basin and, more particularly, the complex hydrological inter-relationships within the flood-plain itself, severely complicate any assessment of the quantity of water available for the needs of plants. This, in turn, means that the irrigation requirements of river meadows must be very carefully judged. The normal estimations, based solely on climatic and soil moisture data, are, in these conditions, insufficient since a rapid rise in water-table level can bring abundant supplies of moisture within reach of the plant roots. Thus, all the factors which can affect the height of the water-table should properly be taken into account when the water 'balance sheet' is drawn up, in order to prevent the possibly harmful results of over-irrigation.

ULTRASONIC RELAXATION IN A MICELLAR SYSTEM: *n*-OCTYLAMINE–WATER

By J. F. McKELLAR* and J. H. ANDREAE†

Akers Research Laboratories, Imperial Chemical Industries, Ltd., Welwyn, Herts

In order to extend our investigation of hydrogen bonding in aqueous solutions of simple amines[1,5] to micellar systems, we have made ultrasonic absorption measurements on the system *n*-octylamine–water. The phase diagram[2] for this system shows, at 20° C, two regions of isotropic solution at low (0.00–0.03 mole fraction) and high (0.40–1.0 mole fraction) amine concentrations, suitable for sound absorption measurements. No attempt was made to make measurements in the mesomorphic and two-phase regions at intermediate concentrations because of the possibility of sound scattering.

We have found a correlation between sound absorption and micelle formation which is the subject of this article.

The ultrasonic techniques have been described[1,3]. The sound absorption measurements were made at frequencies between 1.5 Mc/s and 230 Mc/s, and the sound velocity was measured at 2 Mc/s.

As with the primary and secondary amines previously examined[1] the measurements of α/f^2 for *n*-octylamine–water in both isotropic regions could be described by the relation for a single relaxation,

---

* Now at Imperial Chemical Industries, Ltd., Dyestuffs Division, Manchester 9.

† Now at Standard Telecommunications Laboratories, Ltd., London Road, Harlow, Essex.

$$\frac{\alpha}{f^2} = \frac{A}{1 + (f/f_c)^2} + B \qquad (1)$$

where A and B are constants and f_c is the relaxation frequency. Values of μ_{max}, the maximum absorption per wave-length defined by

$$\mu_{max} = \tfrac{1}{2} A\, f_c\, C \qquad (2)$$

were calculated. C is the sound velocity.

The main feature which emerges from the measurements on *n*-octylamine–water is the anomalous variation of μ_{max} at low amine concentrations, when it is compared with that found with the shorter chain amines[1]. It is seen from Fig. 1 that μ_{max} for *n*-octylamine exhibits only a very gradual increase with concentration of amine up to the phase boundary at 0.03 mole fraction. The variation of μ_{max} for *n*-amylamine at 20° C is included for comparison.

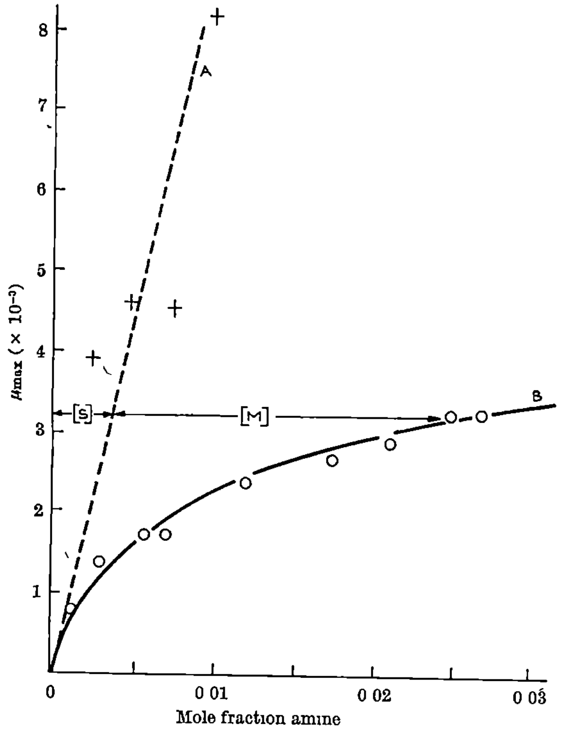

Fig. 1. Variation of μ_{max} with concentration. O, *n*-octylamine (20° C); +, *n*-amylamine (20° C)

Other properties also distinguish the foregoing two systems in this concentration range. The variation in shear viscosity is shown in Fig. 2. It is seen that an abrupt change in the viscosity concentration curve occurs at about 0.007 mole fraction for *n*-octylamine. This suggests that aggregation of *n*-octylamine into micelles occurs in this concentration region and that perhaps it is this property of the system which predominantly influences the variation of μ_{max} in Fig. 1. The viscosity behaviour for *n*-amylamine is similar to that found with diethylamine–water[4].

We shall consider that the mechanism responsible for the relaxation in *n*-octylamine–water is the same as that attributed to the higher frequency relaxation found with the shorter-chain amines (perturbation of an equilibrium involving the hydrogen bonding of unlike molecules[1,4]), and that the consequent sound absorption is due only to unaggregated molecules, as can be assumed for the shorter-chain amines. For the mechanism of hydrogen bonding between unlike molecules, the relaxation frequency f_c is determined by k_f and k_b, the rate constants of the forward and backward reactions[5]. For *n*-octylamine–water containing both unaggregated and aggregated amine (considering that the polar groups are orientated towards the water structure) it is likely that both these species will form hydrogen bonds with the water and give rise to sound absorption. It may be, however, that the rates at which these reactions occur will differ for the two species. This could lead, if the difference were significant, to two distinct relaxational processes, one being due to the association of water and aggregated amine and the other to water and unaggregated amine. This is illustrated in Fig. 3, $\mu_{max}(M)$ and $\mu_{max}(S)$ denote the absorption for the aggregated and unaggregated amine and similarly $f_c(M)$ and $f_c(S)$ denote the respective relaxation frequencies.

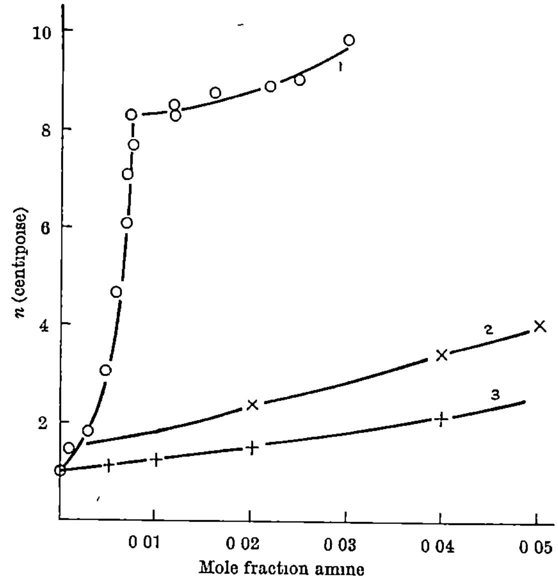

Fig. 2. Variation of shear viscosity with concentration. (1) *n*-octylamine (20° C); (2) *n*-amylamine (5° C); (3) *n*-amylamine (20° C)

From Fig. 1 it is seen that this hypothesis can be examined in a more quantitative manner. If we consider that the sound absorption indicates the concentration of amine, and that to a first approximation the absorption is the same for *n*-amylamine and unaggregated *n*-octylamine (indicated by the broken

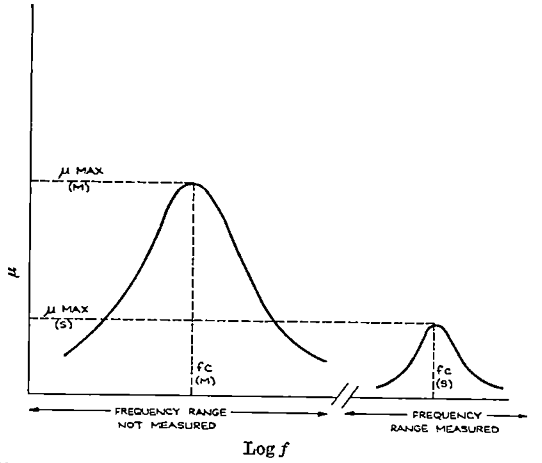

Fig. 3. Sound absorption per wave-length for two relaxing processes

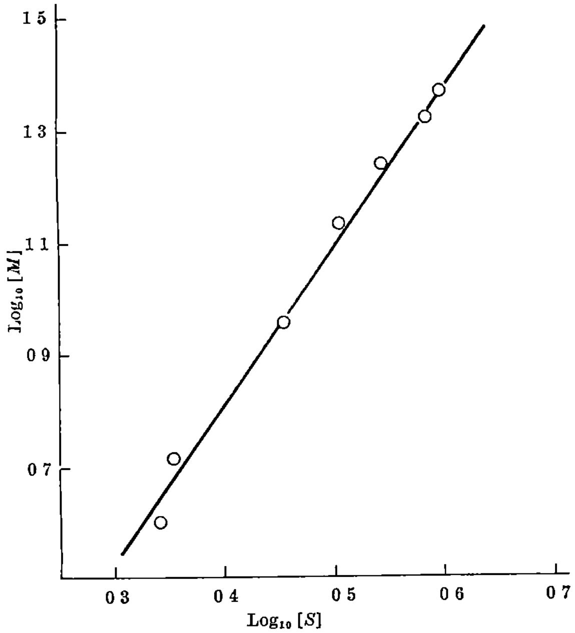

Fig 4 Plot of $\log_{10} [M]$ against $\log_{10} [S]$ for *n*-octylamine–water Temp = 20° C

line *OA*) we see that at a mole fraction of 0 025 the concentration of unaggregated and aggregated *n*-octylamine is given by [*S*] and [*M*] respectively Taking the aggregation reaction as

$$mRNH_2 \rightleftharpoons (RNH_2)_m \qquad (3)$$

where m = number of single molecules per micelle, and equating activities to concentrations, we obtain from the simple law of mass action for un-ionized molecules aggregating to uncharged micelles

$$K = \frac{[M]}{m[S]^m} \qquad (4)$$

In logarithmic form (4) gives

$$\log [M] = m \log [S] + \log [K m] \qquad (5)$$

A plot of log [*M*] against log [*S*] for the mole fraction-range 0 006–0 0275 is given in Fig 4 A straight line is obtained with $m = 3$ (approx) Substituting $m = 3$ in equation (4) an average value of $K = 1\ 35 \times 10^5$ is obtained Again, taking [*S*] as indicated by *OA* (Fig 1) and substituting in equation (5) the values for m and K obtained above we can calculate the variation of [*S*] and [*M*] with concentration of amine This is shown in Fig 1 by the line *0B* which gives a good fit with the experimental results Substituting the value for K in the relation

$$-\Delta G = R\, T \ln K \qquad (6)$$

we obtain $-6\ 9$ kcal per mole of micelles for the free energy of micellization at 20° C

The foregoing treatment gives a reasonably satisfactory explanation for the anomalous behaviour of μ_{max} in *n*-octylamine–water at low amine concentrations Unfortunately, there are few thermodynamic data available on non-ionic micellar systems and none for this system which may be compared with the above values of m and K to test the hypothesis Calculations[6] from diffusion measurements for the paraffin chain salts (which form ionic micelles) have indicated that salts containing 8 carbon atoms in the chain form micelles each containing about 12 molecules The above value of $m = 3$ derived from *n*-octylamine–water suggests, if the interpretation of the ultrasonic measurements is correct, an appreciable difference in size for the two types of micelle

PARENTERAL COPPER IN COPPER-DEFICIENCY DISEASES OF ANIMALS

By A. ASHFORD and Dr S E. MICHAEL

The Crookes Laboratories, Ltd , London, N W 10

COPPER deficiency occurs in farm animals, particularly in cattle and sheep, in various parts of the world The incidence of swayback is a hazard in several sheep-farming areas in the United Kingdom, and hypocuprosis in cattle is also of growing importance, especially during the grazing season Copper-deficiency may be a limiting factor in the economy of sheep production in New Zealand and Australia and losses in fleece value due to this deficiency merit special consideration

Marston[1] has suggested that the most economic way of treating this condition is the parenteral application of copper in such dosage that only one injection per animal is normally required As ionized copper in high doses is toxic, it is necessary to apply the copper in a non-ionized form or in a form in which it is only gradually absorbed from the site of injection so that the level of copper in the blood remains low Examples of the first type which have been used in the past are the highly complexed copper-edetate and copper-hydroxyquinoline disulphonate[2], and of the second type are suspensions of copper glycinate (moderately soluble in water) in non-aqueous media, such as beeswax-oil, whereby absorption is retarded These types are clinically effective, but they are not free from toxicity and they may give rise to irritation and swelling at the site of injection

A somewhat different approach to the problem is, however, possible, and this has been followed in the work recorded here It has been known for a long time that the solubility in water of the very sparingly soluble copper salts of certain amino-acids is greatly influenced by the presence of other amino-acids Hofmeister[3] pointed out that copper glutamate is much more soluble in the presence of glycine than in water alone This increased solubility can be explained by assuming that the copper-ion can be exchanged between the two types of amino-acid

If this exchange can take place between different amino-acids, then a similar exchange might occur between the copper–amino-acid combination and peptides or proteins Assuming this to be so, then copper salts of amino-acids of very low solubility could be introduced into the animal organism by parenteral injection, and it might be expected that the proteins of the body fluids which pass the site of injection would remove some of the copper by exchange with the amino-acid, the copper would thus be transported from the site of injection in combination with protein As the copper in this transport system may never be in a substantially ionized form, the desired clinical effect might be brought about without the toxicity or strong irritation which are characteristics of ionized copper

The assumption of copper exchange between an amino-acid and proteins may be supported by a simple model experiment The copper salt of *dl*-methionine, prepared according to Mueller[4], was suspended in water, saline, pig blood serum or a 2 per cent aqueous solution of serum albumin The mixtures were agitated for 24 hr , the liquors were separated by filtration from the excess of insoluble copper salt, and the copper contents of the filtrates were determined colorimetrically with sodium diethyl dithiocarbamate[5]

Table 1 gives the results so obtained

Table 1

	Copper (μgm /ml)	Colour of filtrate
Water-filtrate	9 4	Colourless
Saline-filtrate	12 0	Colourless
Serum-filtrate	120	Olive-green
Albumin-filtrate	180	Olive-green
Albumin-solution (control)	6	

Inspection of these figures shows that the solubility of the copper salt of methionine is about 1 100,000 in water or saline, but is increased 10–15 times in the presence of serum or serum albumin.

A comparison of the toxicities and irritancies of some soluble and 'insoluble' copper compounds was therefore made, and this was followed by an examination of the metabolism of the copper of the least-toxic compounds Acute toxicity tests were carried out on female albino rats weighing between 70 and 130 gm Intramuscular injections of solutions or suspensions containing 30 mgm copper/ml were made into the right hind-limb Five rats per dose group were used, and they were observed for a period of five days The results of these tests are given in Table 2.

Table 2

Material	LD_{50} mgm Cu^{++}/kgm.
Copper sulphate in water	24–42
Copper salt of glycine in water	10
Copper salt of glycine in 30 per cent gelatine	24
Copper glutamate in aqueous suspension	> 60
Copper salt of methionine in aqueous suspension	> 120

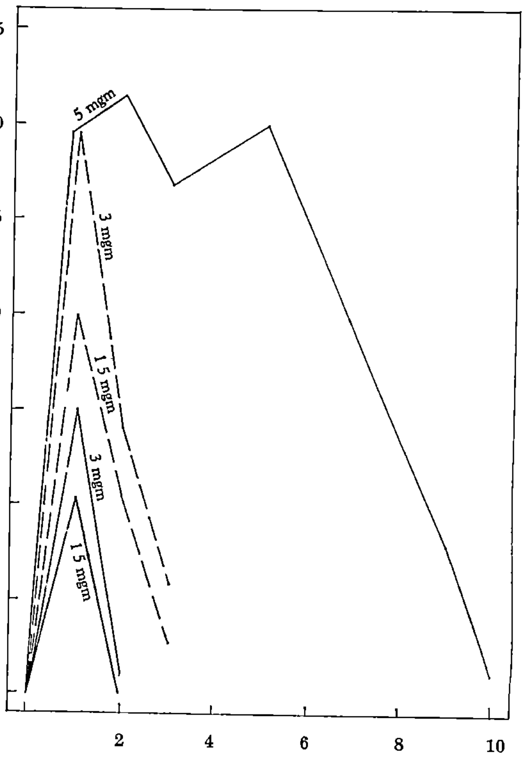

Fig 1 Irritant effects of copper after intramuscular injection into the hind leg of the rat
—, methionine complex, – – –, copper sulphate Doses are given in mgm copper/kgm body-weight

Rather surprisingly, the copper salt of glycine was the most toxic substance tested, and although the use of a delaying medium (30 per cent gelatine) reduced the toxicity to approximately that of an aqueous solution of copper sulphate, the glycine complex is still considerably more toxic than either the poorly soluble copper glutamate or the copper salt of methionine The LD_{50} of the copper salt of methionine also exceeded 100 mgm. copper/kgm when injected subcutaneously into male albino mice (Schneider) weighing 18–22 gm

On the basis of these results, the methionine complex was studied for irritant effects following an intramuscular injection into rats The clinical dose of copper in domestic animals is about 1 5 mgm Cu^{++}/kgm , and the effects of copper injections should be interpreted in the light of this dose Irritancy studies were carried out in female albino rats, the copper complex again being given intramuscularly into the right hind-limb The degree of swelling of the copper-injected limb was assessed by measuring

Table 3

Form and amount of copper injected	No of rats	Total copper injected (mgm)	Copper conc (μgm /gm wet weights) found in injected leg	Copper conc (μgm /gm wet weights) found in liver	Total copper (mgm) found in injected leg	Total copper (mgm) found in liver	Copper (per cent) absorbed	Per cent absorbed deposited in liver
Methionine 1 5 mgm /kgm	10	2 8	3	4	0 2	0 25	93	
Control	6			5		0 32

Control	2			16		0 13		

the increase in limb diameter of the injected leg, compared with the control hind-leg of the same animal. Diameters were measured with calipers. Doses of 1·5 mgm. and 3·0 mgm. Cu^{++} (as the copper-methionine complex) per kgm. body-weight caused a swelling of the limb which was greatest on the day after injection and which regressed completely by the second day. Equivalent doses of copper sulphate caused a bigger initial swelling which took up to 3–4 days to regress. Doses larger than 3 mgm. copper/kgm. caused a much more protracted irritation; for example, a dose of 5 mgm. copper/kgm., as the methionine complex, required 11 days for complete regression (Fig. 1). Histologically, the inflammation evoked by the copper salt of methionine showed a large cellular migration into the injured tissue and the lymph nodes in the limb were enlarged. These effects persisted for a period of at least 17 days. Occasionally, after a dose of 1·5 mgm. copper/kgm. (methionine complex), there was a residual fibrous deposit in the region of injection. Very large doses of the copper salt of methionine may cause necrosis.

The metabolic fate of the injected copper is, however, the most important feature of the problem. It is known that copper is preferentially concentrated in the liver, kidney and bone marrow of the rat, guinea pig, rabbit, dog, cattle and man[1]. We have examined the removal of copper from the site of injection in the rat and its accumulation in the liver. We have found that, after intramuscular injection of copper glutamate or the copper salt of methionine, the copper is largely removed from the site of injection and deposited in the liver. In the experiments summarized in Table 3, 1·5 mgm. copper/kgm. body-weight and 60 mgm. copper/kgm. respectively of the copper salt of methionine, or 60 mgm. copper/kgm. of copper glutamate were injected. Seven days later the rats were killed and the copper contents of injected leg, and of the liver, were determined. Table 3 shows that out of the total copper (of methionine salt) injected nearly all the lower dose and 45 per cent of the higher dose were removed from the site of injection. The absorption of the copper from the glutamate, given in the high dose, varied from 58 to 88 per cent of the amount injected. Varying, but considerable, amounts of the absorbed copper were found in the liver: 20–76 per cent from copper glutamate, apparently more than 100 per cent (probably experimental error) from the copper salt of methionine.

These experiments show that the insoluble copper salts of glutamic acid and methionine are less toxic than ionic copper salts, such as copper sulphate, or less highly complexed compounds, such as the copper salt of glycine. The irritancy also of the insoluble copper complexes is lower than those of the more soluble compounds. Both copper salts are removed from the site of injection and distributed in the body. After injection of larger doses, a considerable part of the copper was found in the liver, thus indicating that the copper is indeed taken up by the body fluids and transported to the target organ. It is important to point out that in these experiments the animals used were not copper-deficient.

On the strength of this investigation, the copper salt of methionine has been introduced with success for the treatment of copper deficiency of cattle and sheep.

TIME-SEQUENCE OF HUMAN CHROMOSOME DUPLICATION

By C. W. GILBERT, S. MULDAL, L. G. LAJTHA and JANET ROWLEY*

Paterson Research Laboratories, Christie Hospital and Holt Radium Institute, Manchester

CHROMOSOME duplication occurs during a part only of the intermitotic cycle time: the period of synthesis of DNA (*S* period). Grain count distributions on autoradiographs with DNA label have indicated that the time sequence of events during the *S* period is largely determined by the fact that DNA is synthesized on discrete large structures—the chromosomes[1]. Consequently, a search has been started to investigate the detailed pattern of chromosome duplication in man, to find out whether it is of random nature or follows a definite time-sequence. Some of the preliminary findings are reported here.

Human peripheral leucocytes were cultured *in vitro*, using the phytohæmagglutinin method[2]: 20 ml. heparinized blood was mixed with 1 ml. of 6 per cent dextran solution and kept at 4° C for 1 h. The supernatant plasma was removed, diluted 1 : 5 with medium 199 (Glaxo). Extra plasma was obtained by centrifuging the sedimented red cells and also was diluted with medium 199. The white cell count was adjusted, by adding this extra medium, to about 1,200–1,400 cells/mm^3. Phytohæmagglutinin was then added; 0·2 ml. of a 1 : 50 dilution of the Difco '*P*' preparation per 10 ml. cell suspension. The suspension was then distributed in 4–5 ml. lots into a number of screw-cap universal containers, and incubated at 37° C for about 66–68 h.

The bottles were then divided into two groups, one labelled 4 h, the other 3 h, before terminating the culture. Labelling was performed by adding 0·2 μc./ml. medium of tritiated thymidine (Amersham, specific activity 2·3 mc./μM). Care must be taken that the cultures should not cool appreciably during the process of labelling. Finally, 'Colcemid' (Ciba) was added, 0·04 ml./ml. medium, 1½ h before terminating the culture by replacing the incubation medium with 4 ml. of 0·95 per cent sodium citrate.

Chromosome preparations were made by the air dry method; these were coated with Kodak *AR* 10 autoradiographic stripping film. The slides were exposed for 3–8 days, processed and stained with Leishman–Giemsa stain. The selected cells were photographed for record, the karyotype analysed,

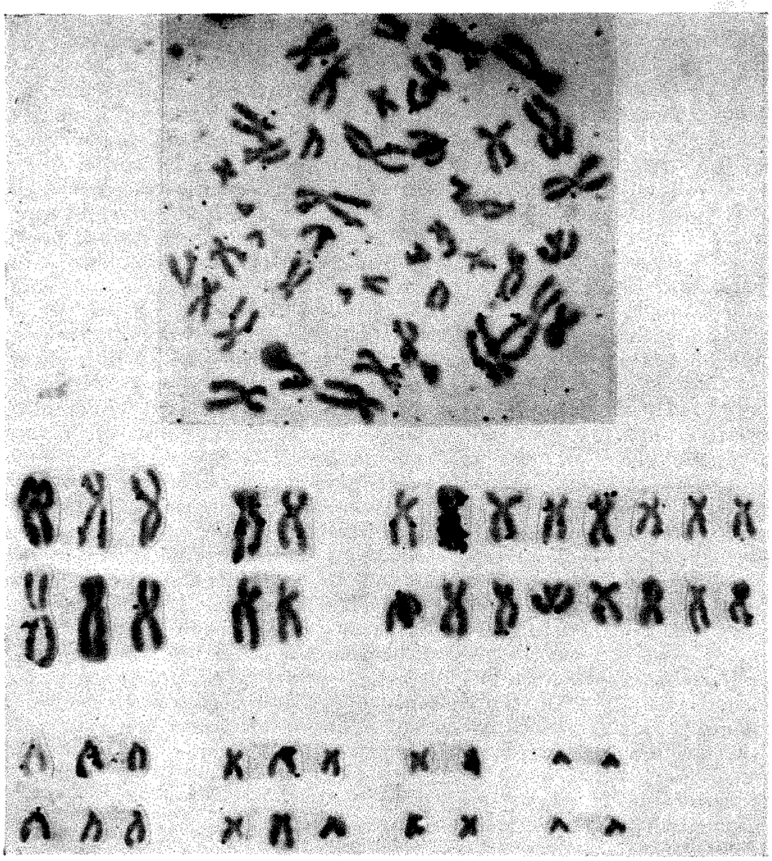

Fig. 1. Autoradiograph of karyogram of human female cell labelled at the end of the S period

and the grains over the individual chromosomes counted and their position noted. Only labelled cells with the best possible morphological picture of the chromosomes were selected for analysis. The selected cells were mostly in late prophase/early metaphase. Classification was carried out according to the Denver system, although we place more emphasis on homologous pairing than on chromosome sizes[3]. Consequently, we have assumed that one can often distinguish chromosome 4 from 5 in group II, and that 6, 10, 11 and 12 are not too often confused with X, 7, 8 and 9, the X chromosomes being more variable than the autosomes. In group IV, chromosome 13, apart from being the largest in the group, also has the longest 'centromere/satellite' region, and chromosome 15, the shortest, is also provided with a more definite euchromatic short arm. Fourteen will thus be left over when the other two are identified. We also assume that 19 tends to be separable from 20 in these early metaphases, although this has not been done with much confidence. Finally, group VII has been arranged on the principle that chromosome 21 has the larger size and satellite.

Like all mammalian cells, the dividing cells in this system also have a 2–3 h period (G_2 period) between the end of the synthesis of DNA (S period) and onset of mitosis. Hence in a 3–4 h incubation time the cells appearing in mitosis at the end of the incubation period must have been near to or just passed the end of the S period. This indeed was indicated by the large proportion of unlabelled mitoses (30–50 per cent). The total duration of the S period in these cells is not known, but grain counts over the labelled mitoses compared with those over the labelled resting nuclei indicated that the mean labelled mitoses contained only about one-fifth of the label, that is, the time spent in S period has scarcely exceeded 30 min. As the S period in most mammalian cells so far studied is of the order of 6–8 h, the labelling system used here represents the very end, the last 30–50 min of that period.

Several cultures were examined in this way, with similar results. The quantitative results presented here are from counts on 33 labelled mitoses in a culture from a normal female, labelled at minus 4 h. A typical autoradiograph and karyogram is shown in Fig. 1.

The grain distribution over the chromosomes of 33 cells was assessed. The arms of the chromosomes were divided into 1, 2, 3 or 4 equal segments depending on the length of the arms and the grains were counted over each segment. The mean density of the grains over each segment was calculated from the relation:

$$\frac{1{,}000s}{Nl}$$

where s is the total number of grains counted over the corresponding segments of all homologues (66 chromosome segments), N the grand total of grains over all chromosomes in all cells, and l the relative length of the segment (1,000 being the total length of all chromosomes in a female cell). The results are shown in Fig. 2 as histograms giving the distribution of grains along each chromosome. The X chromosomes are shown separately. Chromosomes 1, 3, 19 and 20 have almost central centromeres and so the mean distribution over the two arms is shown. In these diagrams the normalization is such that the chromosomes would have a uniform grain density (of unity) if at the period of labelling, the end of S, all the chromosomes had been synthesizing at the same rate per unit length. The distributions are significantly different from this and clearly show the existence of a regular pattern of synthesis.

The most noticeable feature of this pattern is the high number of grains over one of the X chromosomes ('hot' X). Apart from that the larger chromosomes show generally a greater density of labelling than the shorter ones, but there are exceptions. Group II is the most heavily labelled and the short chromosomes 17, 19, 20 and 21 are weak, though 13 has a heavily labelled long arm. Many of the chromosomes, notably 5, 9 and 16, also show marked differences between the two arms, and there is a general tendency for the shorter arm to be the more heavily labelled in the longer chromosomes and the reverse in the shorter ones. Many chromosomes show variations of density along the length of one or both arms. There is no general pattern, and examples of most of the possible patterns can be found. Chromosomes 1 and 13 show a significantly high grain count in the middle of an arm, chromosomes 4, 5, 9 and 17 show

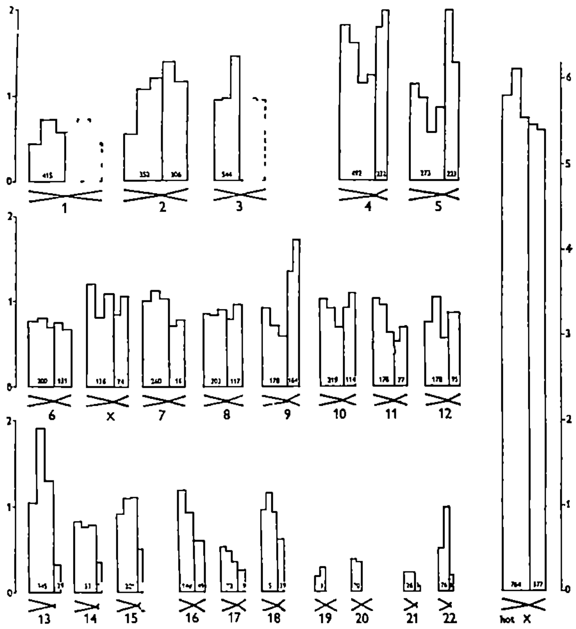

Fig 2 Distribution of tritiated thymidine over chromosomes of human female cell, labelled at the end of *S* period Ordinate shows the linear density of grains normalized so that the average density over all the chromosomes is unity The numbers show the total grain counts over each arm for 33 cells

a gradual increase of grains from the centromere to the end and chromosome 2 shows the reverse Although the short chromosomes have low grain counts, nevertheless the relatively high density of chromosome 22 compared with 21 is significant

The 'hot' *X* chromosome accounts for 14 4 per cent of all the grains on the cells However, there is a significant change in the proportion with the total number of grains over a particular cell This is shown in Fig 3 The points in the figure show the mean proportions of grains over the 'hot' *X* for the five groups of cells with total grain counts between 0–100, 100–200, 200–300, 300–400 and over 400 The line is the calculated regression line, and the slope of this line is significant at a probability of 000 3 The data are insufficient to distinguish a curved from a straight regression line

The total number of grains over a cell probably indicates how near that cell was to the end of the *S* period when the label was applied, the smaller the uptake the nearer the end Thus, as the end of the *S* period is approached the relative difference between the label on the 'hot' *X* and the other chromosomes becomes more marked This indicates that synthesis of the whole of the 'hot' *X* chromosome occurs at the very end of the *S* period

Only in the *X* chromosomes is there a marked difference (heterozygosity) between the two homologues, a detailed statistical analysis failed to show any difference for any other chromosome

An analysis was made of the variance of the grain counts over each chromosome pair For each the following quantity was calculated

$$Y = \frac{2N}{2N-S}\left[\frac{2N}{S}\sum_{i=1}^{33}\left(\frac{a^2+b^2}{n_i}\right) - S\right]$$

where N is the total grains over all cells, S is the total grains over the pair of chromosomes of all cells, a_i, b_i, the grains over the pair of chromosomes of the i-th cell, n_i the total grains over the i-th cell, and the summation is taken over all the cells If each grain were a statistically independent event, this would be a χ^2 of 65 degrees of freedom and its expected value would be 64 5, or about 1 per degree of freedom However, the average value of Y is 2 10 per degree of freedom Thus, the variance of the grain counts is 2 10 times as great as that expected from a Poisson distribution Something of this sort is to be expected, since each β-particle of tritium may produce more than one grain in the autoradiographic emulsion If G is the mean number of grains per β-particle, and if these have a Poisson distribution, then since the β-particles are random events, the variance of the grain counts will be increased ($G + 1$) times Thus, the assumption of a G of 1 1 will fully account for the observed variance The quantity $Y/2$ 1 will then be a χ^2 of 65 degrees of freedom and the calculated values for the 23 chromosomes (excluding the 'hot' *X*) scatter about the mean value of 64 5 in the range to be expected for a χ^2 This may therefore be regarded as some internal evidence of the consistency of pairing and identification of the chromosomes For example, if the chromosome pair 13 and 14 or 21 and 22 which show markedly different intensity of labelling had been interchanged frequently, then larger values would be expected for the χ^2 for these chromosomes

The real differences in the intensity of labelling of the different chromosomes or parts of the chromosomes, together with the constant variance of the grain count, suggest a very consistent pattern of replication of the chromosomes for all the cells of this culture

The same analysis of variance of the grain counts over the 'hot' *X* shows a considerably greater variance even after allowing for the fitting of the regression line This is probably a real biological variation and expresses the fact that the lateness of the 'hot' *X* chromosome varies somewhat from cell to cell

The most striking observation is the finding of an exceptionally heavily labelled chromosome in group III It was, of course, of crucial importance to decide on the identity of this chromosome, especially since the intensity of label could introduce some bias in classification, sometimes even obliterating morphology, a feature not affecting the other chromosomes Ideally, one might classify the chromosomes before putting on the film, but this obviously would involve a great deal of wasted effort in analysing afterwards unlabelled cells

The procedure adopted here was to pair up homologues[3], which resulted in two chromosomes being left over, one of which in each case was the 'hot' chromosome This chromosome pair with the

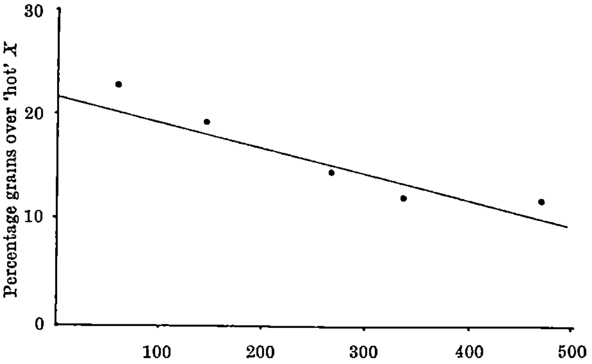

Fig 3 Change of relative intensity of labelling of 'hot' *X* chromosome with total labelling of the cell

expected size difference, fitted in between 6 and 7 in group III, that is, the position of the X chromosome

Furthermore, as the other chromosomes show a consistent pattern of label, it is reasonable to suspect that that chromosome which is exceptionally heavily labelled is the same chromosome in all cases

The sex chromatin in human females (the Barr body[4]) is now generally believed to be produced by the heteropycnosis of one of the X chromosomes[5] (or part of it)[6] while the other X remains isopycnotic like the autosomes This heteropycnotic behaviour is transmitted to the daughter chromosomes[7] from one cell generation to the next Heteropycnotic differentiation of the X is presumably established early in ontogeny[8,9], and may apparently involve either of the two X chromosomes in different regions of the embryo, resulting in a mosaic pattern when the two chromosomes carry different dominant genes[10] The general implication is that the heteropycnotic X chromosome is genetically inactive and that only one active X chromosome is required for the normal function of the cell Chromosome 'activity' is, however, expressed in two ways (*a*) genetic activity expressed in RNA coding, and (*b*) chromosome duplication (DNA synthesis)

Morphologically, the heteropycnotic state appears as a more tightly coiled chromonema, and it is possible that a chromosome in such a condition cannot reveal much surface for coding activity It would also follow that when chromosome duplication takes place such a chromosome may be delayed compared with isopycnotic chromosomes We found this X chromosome not only many-fold 'hotter' than the other chromosomes but that it often had a higher grain density than any chromosome region observed in interphase nuclei This must mean that the 'hot' X synthesizes DNA more or less simultaneously along its whole length and has, therefore, a very short S period, shorter than any other chromosome of similar size

Our findings are in good agreement with earlier reports on this subject in the literature Taylor, using embryonic tissue cultures of Chinese hamster, has already demonstrated such a delay in DNA synthesis of sex chromatin[11] More recently, Morishima, Grumbach and Taylor[12] have reported on a late synthesizing X chromosome in human female as well as on other late synthesizing chromosomes, one each in groups II, IV, VI and VII German[13] also reports a 'hot' chromosome in group III Although these authors do not present quantitative information, their conclusions are basically similar to those reported here

Structural heterochromatin is frequently associated with regions of spontaneous or chemically induced chromosome and chromatid breaks[14-16] By comparison with data collected of the spontaneous somatic breakage pattern in man, it appears that the peak spots fit in well with the highly labelled regions on the chromosomes in the late stages of DNA synthesis Owing to the relatively low grain counts in the present series, however, this cannot be statistically proved Labelled chromatid breaks were, however, observed, especially in the 'hot' X chromosome, and it seems that tritiated thymidine applied at the end of the S period provides a method of producing breaks in one of the X chromosomes with a high yield This could be checked simply by the study of variation in Barr body sizes in subsequent cell generations, which may also give further information about the structure of the Barr body

Since spontaneous chromatid breaks or gaps are more or less open, it may be that they are due to interference with DNA synthesis at the end of the S period when no further time is available for their restitution

Certain chromosome translocations are known to occur with an unexpected high incidence as compared with others It is difficult to imagine a translocation to occur between chromosome regions which are not synchronized in their DNA synthesis If we now consider the particularly 'cold' chromosomes at the end of the S in the present series (that is, 21, 19, 17 and 14) we find that three of these may be involved in translocations which are mechanically stable and viable for generations[17,18] The translocations usually associated with mongolism are 21/13–15 and 21/21 (refs 19 and 20) Although it is a fact that chromosome 21 causes mongolism when in trisomic state[21], it is doubtful that the morphology of the translocation chromosomes has been worked out satisfactorily From the labelling pattern reported here it appears that chromosome 14 may be the most likely one in group IV for a synchronized exchange with chromosome 21 The mechanical fitness of these translocation chromosomes may be due to their having arisen in early S, allowing sufficient time for a solid repair at the exchange points The association of satellited chromosomes on the same nucleolus must further increase the probability of translocations

In contrast to the heterozygosity in chromosome labelling in the human male reported by Lima-de-Faria *et al* [22], we found no evidence of such a phenomenon apart from the X pair in the female The degree of heterozygosity observed was no more than expected from the spread of grain count distribution As a matter of fact, the heterozygosity is so negligible that a reasonable correct classification of chromosomes based on their labelling properties seems to be a major feature of the present report Our results support well the Denver classification with emphasis on homologous chromosome pairing rather than on actual chromosome length It has been stated previously that the X chromosome is relatively more variable in size than are the autosomes in group III This is also borne out by the present series Of the two X chromosomes, the 'hot' X is usually the smaller, is often bent, and it may be found in a peripheral position suggestive of the Barr body In the more contracted metaphases the size difference between the two X's tends to disappear, which indicates that the cold X catches up in contraction with the 'hot' X

The choice of early metaphases has given a better grading of the small chromosomes, confirming the old observation that these contract relatively earlier than the longer ones This principle may now be linked with their generally earlier completion of duplication, with the exception of chromosomes 13 and 22

Differential grain counting along the chromosome emphasizes the asynchronous replication of different chromosome parts, but gives little support for a 'zipper' fashion pattern of chromosome duplication from telomeres towards centromeres If the centromeres with adjacent heterochromatin are the last to duplicate it is not a striking feature This may, however, be caused by the tapering of the chromonema in these constrictions Over-exposure of the autoradiographs of weakly labelled mitoses may be necessary to elucidate final localizations such as the significance of the radioactivity over the heterochromatic band in the 'cold' X chromosome

This work will be extended back into the earlier part of the S period in order to map out the complete time sequence of synthesis for the entire chromosome complement in man We have mentioned here some of the possibilities that this technique offers, and one may be justified in expecting some important findings with this 'functional' approach to chromosome physiology, findings possibly involving differences between normal and pathological cells, or minor differences between races of man

TRANSFER OF DEOXYRIBONUCLEIC ACID ACCOMPANYING THE TRANSMISSION OF COLICINOGENIC PROPERTIES BY CELL MATING

By Dr SIMON SILVER* and Dr HAROU OZEKI†

Department of Biology, Massachusetts Institute of Technology, Cambridge, Mass

MANY strains of Enterobacteriaceae produce bactericidal protein substances called colicines The genetic determinants for the synthesis of colicines (colicinogenic factors) behave, under some conditions, as autonomous particles which can be transmitted during conjugation independently of the bacterial chromosome[1-3]

There has been no direct evidence concerning the chemical nature of the colicinogenic factors Analogies with prophages[2,4] suggest that the factors consist of DNA Some colicinogenic factors are transducible by DNA-containing phages[3,5,6] Attempts to determine the DNA content of colicinogenic factor E_1 by phosphorus-32 suicide experiments, however, were unsuccessful[7] By combining the high-frequency colicinogeny-transferring (HFC) system[8] with a method of measuring material transfer[9] we have been able to measure DNA transfer accompanying the transmission of colicinogenic factors I, E_1 and E_2

Radioactive HFC donor preparations[8] of *Salmonella typhimurium LT*-2, mutant *cys D-36*, were prepared as follows tryptone broth containing ^{14}C-thymidine, ^{14}C-uracil or ^{14}C-leucine was inoculated with a mixture of 1 part of a culture of strain *cys D-36* (I) and 20 parts of either *cys D-36 col*$^-$ or *cys D-36* (E_2) or *cys D-36* (E_1) (E_2) After overnight incubation at 37° C , the cultures were diluted four-fold in fresh radioactive broth and incubated for an additional 2 5 hr (with aeration by shaking during the last hour) This procedure gave preparations which transferred either factor I, or factors I and E_2, or factors I, E_1 and E_2 respectively Radioactive cells of *cys D-36 col*$^-$ were prepared in an analogous way, leaving out the inoculum of *cys D-36* (I) An overnight culture of the recipient strain *Escherichia coli* *C*600/I, E_1, E_2 (resistant to all these colicines) was diluted 1 10 with fresh non-radioactive broth and incubated at 37° C for 2 5 hr with aeration by shaking The cultures were centrifuged, washed and re-suspended in broth at densities about 10^9 cells/ml Samples of 3 ml each of donor and recipient cultures were mixed in 500-ml Erlenmeyer flasks and incubated for 75 min at 37° C The mating mixtures were assayed for the frequency of transfer of the various colicinogenic factors[3], centrifuged and re-suspended in 4 ml of fresh broth

With duplicate samples, the *E coli* recipients were disrupted by the addition of a large excess of *T*6 phage (to which *S typhimurium* is resistant) in the presence of DNase After 15 min at 37° C , when lysis-from-without was complete, the lysates were filtered through 'Millipore' filters Any radioactivity which had been transferred from donor to recipient during mating would be released by lysis and could be measured in the filtrates Controls were run to test for spontaneous and phage-induced lysis of the donor strains Chromosomal transfer in these matings is either completely absent or at such a low level as not to interfere with measurement of colicinogenic factor transfer[10]

Thymidine (for DNA) transfer was measured with four different preparations of donor *S typhimurium* strains a non-colicinogenic strain, a mixture that transferred only factor I, a mixture that transferred factors I and E_2, and a mixture that transferred I, E_1 and E_2 The results of several experiments are shown in Table 1

By taking the differences between the levels of transfer, using paired experiments to eliminate some systematic errors[9], one can estimate the amount of DNA associated with the individual factors as I = 0 7 per cent, E_1 = 0 8 per cent and E_2 = 0 4 per cent of the DNA of the donor cells The lower limit of detectability in these experiments is about 0 3 per cent transfer per mating donor so these numbers can be considered only order of magnitude estimates

(I) (E_2)	10	0 69	0 20	0 49 ± 0 31	45	1 1
	12	0 55	−0 02	0 55 ± 0 15	100	0 55
(I)	10	0 29	0 07	0 22 ± 0 07	31	0 71
	12	0 32	0 30	0 02 ± 0 13	13	—
col$^-$'donor'	12	0 09	0 02	0 07 ± 0 02	—	—

A, difference between the average per cent of the radioactivity found in the filtrates with and without phage, *B*, difference between the values from col *A*, mating minus control, *C*, *col*$^+$ *E coli* after 75 min mating/*S typhimurium* at time of mixing, *D*, value in col *B* divided by value in col *C*

From the data of ref 11 for DNA per cell of *S typhimurium*, and assuming that only one copy of each factor is transferred, the estimates for the sizes of each factor correspond to $I = 6 \times 10^4$, $E_1 = 7 \times 10^4$ and $E_2 = 3 \times 10^4$ nucleotide pairs These estimates may be somewhat smaller than the true values if non-radioactive factors have been transferred during a second round of conjugation, or larger than the true values if more than one copy of each factor is transferred during mating

Colicinogenic factors E_1 and E_2 (but not I) can be transduced by phage P_{22} (refs 3 and 5) (which has a DNA content of 7×10^4 nucleotide pairs[12]) This sets an upper limit for the size of factors E_1 and E_2, which agrees with the order of magnitude estimates from the present work This agreement, along with the apparent correlation between the amount of DNA transferred and the number of types of factors transferred (3 > 2 > 1 > 0), suggests that the DNA transferred comprises the colicinogenic factors and that only one copy of each factor is transferred Lavallé and Jacob[7] have shown from phosphorus-32 suicide experiments that colicinogenic factor E_1 is very resistant to phosphorus-32 decay and estimated that it cannot contain more than 5×10^3 nucleotide pairs of DNA and possibly less If one takes both our estimate and Lavallé and Jacob's limit at face value, about 14 copies of the E_1 factor would have to be transferred in each mating pair

There are, however, several reasons why Lavallé and Jacob may have under-estimated the size of the colicinogenic factor Rapid multiplication of the colicinogenic factor after transfer and prior to freezing would result in a pronounced under-estimate (Preliminary experiments[13] indicate that this is the case) The suicide experiments measured the size of the colicine-producing gene while the colicinogenic factor might contain additional genes, including those involved in transfer by conjugation, induction of colicine formation and resistance to colicine

Experiments using ^{14}C-uracil (for RNA) and ^{14}C-leucine (for protein) did not show measurable transfer, but the resolution was such that genetically (or physiologically) significant transfer could have remained undetected The limit for the transfer of uracil-radioactivity was about 0 3 per cent per donor in each case However, since there is about six times as much RNA as DNA in the donor cells this limit represents about 3×10^5 nucleotides—the same as the amount of DNA transferred The limit for leucine transfer was similar, and there is more than ten times as much protein as DNA in the donor cells In conclusion, we have evidence for DNA transfer but no reason to exclude RNA and/or protein from the colicinogenic factors

INFECTIVE RIBONUCLEIC ACID COMPONENT OF CELLS INFECTED BY ENCEPHALOMYOCARDITIS VIRUS

By A. J. D. BELLETT, A. T. H. BURNESS and F. KINGSLEY SANDERS

Virus Research Unit, Medical Research Council Laboratories,
Carshalton, Surrey

HUPPERT and Sanders[1] reported that infective ribonucleic acid (RNA) could be recovered from encephalomyocarditis (EMC) virus-infected mouse ascites cells maintained *in vitro*, or from the culture fluid into which such cells had released virus When the virus was deposited by centrifuging this fluid at 100,000*g* for 1 h, little infective RNA could be recovered from the sediment, though large amounts could still be obtained from the supernatant When the sediment was washed by a further cycle of centrifugation, no infective RNA could be obtained from it This result led to the idea of a component, smaller or less dense than the virus, from which infective RNA could be prepared[1–3] Experiments reported here suggest that, although a viral precursor may exist, the results which led Huppert and Sanders to postulate its existence can be interpreted in another way

Huppert and Sanders prepared RNA by the technique of Schuster *et al* [4], that is, by three extractions with water-saturated phenol at 4° C, followed by ether extractions of the aqueous phase to remove phenol, ether was removed by bubbling nitrogen through the preparation, which was injected into mice to estimate its infectivity We now use the technique described by Sanders[2], which differs in that nickel ions are present during preparation, and that instead of using ether to remove phenol, RNA is precipitated directly from the aqueous phase by

BRITISH ASSOCIATION MEETING IN MANCHESTER

INVESTMENT IN SCIENCE*

By Sir JOHN COCKCROFT, O.M., K.C.B., O.B.E., F.R.S.
The Master, Churchill College, Cambridge
President of the British Association

ALMOST half a century has passed since the British Association met in Manchester under the presidency of Prof. Arthur Schuster. This was the end of the period which had been dominated in Manchester by Rutherford, Horace Lamb, 'Sammy' Alexander, the philosopher with beard and bicycle, Tout, the historian, Chaim Weizmann and other giants. I was fortunate in spending two terms in the University under the influence of some of these great men before I went off to the War.

The Physics Section of the British Association met in 1915 in Rutherford's Laboratory under the presidency of Sir Frank Dyson, and Rutherford wrote to Boltwood that they had had very good discussions on isotopes led by Soddy, on the classification of stars by Fowler and on thermionic emission by O. W. Richardson. The Braggs, father and son, talked about X-rays and crystal structure, and A. N. Whitehead spoke on time, space and relativity, so in spite of the War the physicists had a good feast.

Bohr was still working in the Laboratory, and by this time his theory of atomic structure was gaining acceptance, and Rutherford had taken over from Marsden experiments on the projection of hydrogen particles by α-particles. He wrote to Bohr in December 1917:

> "I occasionally find an odd half hour to try a few of my own experiments and have got, I think, results that will prove of great importance but a great deal of work will be required to make sure".

By June 1919, however, he was able to publish the result of his four years of work and to be pretty certain that nitrogen atoms were disintegrated by the impact of his α-particles. These experiments were to lead twenty-three years later to the first controlled release of nuclear energy in Fermi's atomic pile and fourteen years later again to the first large-scale nuclear power station in Britain—the result of half a century of work by physicists of many nations and by our engineers.

While it is natural for me to think of physics in Manchester, we should not forget the line of illustrious chemists and biologists who have worked here and moved on to fertilize and inspire other universities, especially the Universities of Oxford and Cambridge.

During our week here we shall be reminded by our programme that Manchester has long been famous for activities other than science. The Hallé Orchestra is to entertain us and *The Guardian*, true to the tradition of C. P. Scott, will, as always, be describing our discussions. I am speaking then in an environment which has a long tradition of pioneer work in science and technology so I am going to talk about "Investment in Science"—a subject which is more important to our country to-day than it has ever been. If we look back over the forty-seven years since the Manchester meeting we can see that our contribution to basic science compares well with that of any other country, while in technology we have had many notable successes, including radar, jet engines, antibiotics and polymers. In the next half-century, when we have to face the increasingly competitive world of the Common Market, what are the prospects of doing as well or better?

If we look forward to the prospects for pure science, we see that it is in an intensely creative phase. Rutherford's burning desire to learn the innermost secrets of the atom is shared by the generation of his grandchildren. The primitive nuclear particle accelerators of Rutherford's later years which produced hydrogen nuclei with energies of a few hundred thousand volts have been succeeded by enormous nuclear accelerators producing particles of 100,000 times greater energy at 10,000 times the cost. When these beams of very energetic protons collide with other nuclei, they create in the intense field of force of the collision many different members of the nuclear underworld, often known as elementary particles—particles which live for a very short time and often then change into other particles, which in turn may change again until we recognize a well-known particle such as an electron or neutron.

In the immediate post-War years, the invention of the synchrocyclotron producing protons of 300 or 400 million volts enabled us to produce large numbers of the so-called pi-mesons, and to study the forces they transmit, forces which stick the components of atomic nuclei together and are closely connected with the enormous energy stored in atomic nuclei. The invention and construction of the proton-synchrotron or 'Cosmotron' at Brookhaven in the early 1950's increased available proton energies to 3 billion volts, and these protons produced particles heavier than protons known as hyperons, always accompanied by the production of another variety of particles known as K mesons The hyperons and K mesons became known as 'strange particles', since a new classification known as 'strangeness' was introduced to specify their genetic properties A further increase of energy to 6 billion volts in the Berkeley Bevatron enabled us to create anti-matter and to study the physics of anti-matter Anti-protons are produced in pairs with ordinary protons and so are anti-neutrons and anti-hyperons These anti-particles live until they collide with a normal particle, when they annihilate each other, signalling the event to the observant physicist through showers of mesons So we are now able to study the physics of anti-matter by transmitting anti-protons in very large numbers several hundred metres through evacuated pipes to the so-called bubble-chambers full of liquid hydrogen waiting to study their behaviour

---

* Presidential address delivered in Manchester on August 29 and to be published in the September issue of *The Advancement of Science*, 19 (1962–63).

A year ago we thought we might have discovered all the members of the elementary particle family, 17 in all with 17 anti-particles, and then, as so often happens, the veil of Nature was lifted again and a new variety of still more ephemeral particles was discovered by experiments in the giant accelerator at Berkeley Some of these ephemeral particles seem to be excited states of the previously known hyperons with masses up to twice the mass of the proton They live for times of about 10^{-22} sec, just long enough to escape from the nucleus and then break up into more familiar particles, which in turn can change Other similarly ephemeral particles have been found with masses between the proton and pi-mesons which seem to be assemblies of the mesons An understanding of these particles and events of the nuclear underworld, connected as they are with the basic forces of the Universe, present a tremendous challenge to the human intellect If we succeed, our understanding of the physical Universe will be greatly enriched, as it has been enriched in the past by Newton's theory of gravitation, Bohr's theory of the nuclear atom, and by wave and quantum mechanics The study of elementary particles is likely to continue to be in the forefront of physics for several decades and will continue to attract many of the world's best scientists There is, therefore, good reason for maintaining our present heavy investment in this branch of science

While this work with very-high-energy particles goes on, another group of nuclear physicists working with less energetic particles of very precisely defined energies are exploring the detailed structure of the nucleus and its vibrations and oscillations and are also exploring the nuclear processes which lead to the evolution of the elements in the stars So we now know how this evolution starts—by fusing together hydrogen nuclei in a sequence of processes to form helium—and how, much later in the life of a star, as it gets hotter, helium nuclei fuse together to form heavier elements, and this can go on with ever-increasing temperatures until the terrific nuclear explosion of the supernovæ occurs In these explosions the very heavy elements are born

At the Rutherford Jubilee Conference last year Prof W A Fowler reminded us that in 1929 Rutherford estimated the age of the Earth as 3 4 billion years from calculations on the relative abundance of uranium isotopes This was a very good estimate, for the most recent work now estimates the time at which the Solar System began condensation from interstellar gas as 4 7 billion years The age of our Galaxy must be longer to provide time for the synthesis of all the elements, and estimates of its age have now been stretched out to between 7 and 15 billion years The combined efforts of the radio and optical astronomers have within the past two years identified a far distant galaxy, the light and radio waves of which have taken between 5 and 6 billion years to reach us So there is evidently still scope to reach farther and farther out into the boundaries of the Universe In this new branch of astronomy, Lovell at Manchester and Ryle at Cambridge have been world pioneers, and we look forward with great interest to our visit to Jodrell Bank this coming week Optical astronomers are also moving out into space to avoid the interference to their measurements by the absorption of ultra-violet and X-rays in the atmosphere, so there will soon be an 8-in. diameter telescope circling the Moon, and later a 50-in diameter telescope circling the Earth in a 24-h orbit, stabilized to a second or so of arc and transmitting information back to earthbound astronomers by telemetric signals Astronomy from being a poor, neglected subject in Great Britain, reckoning its budgets in thousands of pounds a year has now combined with space science to rival nuclear physics, with budgets in Britain soon likely to approach £5 million a year, and like nuclear physics driven by economic necessity as well as scientific interest to collaboration first with the United States and in future with Western Europe

In Britain and in the world generally solid-state physics attracts as many research workers as nuclear physics, and their achievements, while less glamorous and less publicized, have been great and perhaps of more immediate practical use They have been helped, like the nuclear physicists, by the feed-back from technology producing ever more powerful and discriminating instruments

Electron microscopes of high resolution make visible imperfections in crystal planes of metals and especially those known as dislocations The ease with which dislocations move through metals determines their ductility, and we now understand why metals change their properties with increasing age, why they become more brittle at lower temperature and how impurities affect them Observations of dislocations in uranium metal have recently enabled us to understand why uranium metal crystals grow in one direction under irradiation and shrink in another, a phenomenon of considerable importance in nuclear power stations Recent developments have even made it possible to obtain photographs showing individual atoms in a crystal array and to observe the disturbances produced in the array by the impact of particles

Another branch of solid-state physics, the study of semi-conductors, is now in a rapidly developing stage Starting as an academic subject in the 1930's it has led to the development of transistors, to rectifiers of increasing importance in power generation, to detectors of infra-red radiation of great virtuosity, to devices for producing refrigeration, to solar batteries and many other products

The Earth and environmental sciences are in an equally lively state Geophysicists are preparing to drill the Mohole, a hole 6 km deep through the Earth's crust to the Mohorovičić discontinuity between crust and mantle The recent discovery that the Earth can oscillate like a bell but with a few vibrations an hour promises to throw new light on its inner-structure Oceanographers believe that more extensive studies of the nutrient content of the deep ocean and methods of increasing the turnover could lead to greatly increased fish protein production which at present provides only about 1 per cent of the Earth's food Recent studies of the ocean floor show vast reserves of minerals, especially nickel, cobalt, copper Meteorological science and forecasting will be greatly improved in the future with the advent of more powerful computers and by observations of cloud formations and hurricanes from satellites such as *Tiros*

Recent discoveries in the life sciences have been no less notable and have been greatly helped again by the developments in techniques such as high-precision X-ray crystallography, the electron microscope, chromatography, radioisotopes Among the most important developments of the past decade has been the discovery of the general chemical structure of the giant molecules, known for short as DNA, which determine our hereditary characteristics Watson and Crick, from X-ray data, concluded that the DNA molecule consisted of two intertwining helices containing several million atoms Connecting the two helices like rungs of a ladder are pairs of four kinds of side groups called bases The sequence of these bases provides the genetic code, the genes of classical genetic theory which are now thought to consist of several hundred of these bases Within the past year workers in the Molecular Biology Unit at Cambridge have suggested that a group of three bases provides the information required to fabricate one of the amino-acids in the twenty which constitute a protein molecule Nerenberg and Ochoa discovered which bases are involved in fabricating a number of these amino-acids Kornberg has gone further and actually synthesized DNA by putting the four fundamental monomers into a test-tube together with a little bit of DNA from a living cell and a catalyst This is the first step in the artificial synthesis of genes Biochemists can also induce mutations in the genetic material by specific chemical agents and geneticists can now relate a severe genetic defect such as congenital anæmia to one amino-acid out of place in a protein molecule This work is a remarkable example of inter-disciplinary collaboration which is becoming more common in science Prof P B Medawar has said that

> “ this work considered as a whole is one of the most glorious episodes in biological research In the very remote future this discovery puts it in our power in principle to exercise a primary and direct control over genetic makeup and even to secure a direct and fundamental cure of inborn disorder”

Another great biological development started with the work of Hevesy in 1922 when he used radioactive lead as a tracer to study biological processes The use of nuclear reactions to produce tritium, radiocarbon and a multitude of other tracers has greatly extended the range of these tools and enabled the biochemist to unravel the very complex processes of living organisms, to show that the whole of the components of our bodies are in a general state of flux and to show how the breakdown of a single step in the complicated chemical chain can lead to disease

One of the most important problems of the next half-century is the control of human fertility and the provision of an increasing supply of human foodstuffs to outstrip the doubling of world population, which seems to be regarded as inevitable in this period The biochemists seem now to be making progress in fertility control, and the application of well-known technology to increase agricultural production in underdeveloped countries may be supplemented by turning fishing from a hunting to a farming operation and by new approaches to providing protein for human food

Biology seems, in fact, to be in a rapidly advancing, almost revolutionary phase, and it is important that its full potential should be realized by increased support

While pure basic research provides the essential pool of new knowledge from which, sooner or later, practical developments follow, objective basic research, searching for applications of new knowledge and followed by applied research devoted to a specific project, are among the principal promoters of economic growth to-day So investment in such research should be regarded as of comparable importance to investment in plant and buildings

One of the most spectacular examples of economic growth achieved in this way has been the development of the transistor industry Twelve years or so ago I visited the Bell Telephone Laboratories in New Jersey and saw scientists drawing single crystals of very pure germanium from a molten mass These very pure crystals were seeded with small quantities of vital impurities and then cut up to form the transistors which are now most familiar to us in our portable wireless sets Their influence on the development of electronics has been very great Their great reliability and small power requirements has led to a reduction in size and a great increase in reliability of electronic equipment Without them, space science and space travel would scarcely have been possible They have also made possible the very much more powerful next generation of computers, such as the *Atlas*, the first model of which we are to see at the University this week—a remarkable example of a combined research effort between university scientists and industry Computers are playing a creative part in the development of sciences such as molecular biology, high-energy nuclear physics, the study of stellar evolution, plasma physics, theoretical chemistry and many other branches The University of Cambridge alone has 100 computer users They are becoming an indispensable tool for design of complex equipment such as aircraft, nuclear power stations, and are even penetrating ship design They are becoming important in the control of industrial organizations and they are being used in studies of our economy and may, one day, help to decide the arguments between the expansionists and the restrictionists—we hope to our great benefit

Transistors are only one of the numerous new products of research into solid-state physics Eight years ago, workers in the General Electric Laboratories at Schenectady converted graphite into diamonds by applying a pressure of 100,000 atmospheres and temperatures of 1,600° C together with a catalyst. To-day synthetic industrial diamonds are made on the scale of tons per annum while diamonds as large as one carat have been made So a single laboratory study produced a new product valued at more than 100 million dollars a year

Until very recently, the phenomenon of metals losing their resistance to the passage of electrical current at temperatures near absolute zero—the phenomenon of superconductivity—was an academic subject, pursued almost entirely in university research laboratories Within the past two years important practical applications of superconductivity seem to be emerging The Bell Telephone Laboratories discovered that an alloy of tin and niobium remains superconducting in magnetic fields of up to 120,000 gauss, and already superconducting coils have been built to produce magnetic fields of more than 40,000 gauss with practically no power requirements So the strong magnetic fields required for many experiments in nuclear physics, controlled fusion research and other subjects are likely, in future, to be produced in this way We can even think of the possibility of reducing the loss of power in transmission of electrical energy by using underground superconducting cables, though this would certainly depend on further reducing the cost of cooling to these very low temperatures The next generation of very fast computers may well use for their powerful memories 'cryotrons' containing a multitude of thin superconducting metal films in which current flow can be reversed in a thousandth of a millionth of a second, thus changing the information stored

Another important application of solid-state physics, the so-called optical 'maser', has also come from the Bell Telephone Laboratories during the past two years Maser is a short word for microwave amplification by stimulated emission of radiation The principle of atoms being raised to excited states by absorption of radiation, and afterwards being stimulated by radiation to give out their stored energy, has been known in science for a very long time The maser consists of a synthetic ruby crystal containing chromium ions which can absorb and store light in excited states of the chromium atoms After a time the stored energy is emitted in a powerful short flash, which in some cases has reached the equivalent of 1,000 kW in intensity The radiation is emitted in an extremely narrow frequency band, and the beam of radiation can have a divergence of less than one minute of arc Already this has been used to illuminate an area of two miles diameter on the Moon and reflexions observed The very narrow, powerful beam can pierce holes in refractory metals, since a volume having a diameter of a hundredth of a centimetre can be raised to a temperature of about 8,000° C There will be applications in biology and many other fields, so again new vistas open

Equally important developments are proceeding in the field of energy Modern prospecting methods continue to discover vast new deposits of fossil fuels Uranium, from being an extremely scarce commodity ten years ago, has now, for a time, become almost too abundant At the same time, the cost of converting heat to electricity falls year by year, perhaps stimulated by the coming competition between power stations fuelled by coal and oil, and power stations fuelled by uranium Nuclear power is a good example of the way a great industrial application draws on the knowledge created by forty years of basic research in nuclear physics, followed up with intensive applied research once a clear goal appeared Since our fuel requirements for electricity production are forecast to increase from the present level of 60 million tons of coal a year to the equivalent of 180 million tons by the end of the 1970's, and it seems unlikely that more than 100 tons of our home coal production can be used for electricity production, it seems likely that nuclear power developed in Great Britain will increase from the 5 million kW output forecast for 1968 to much higher levels in the 1970's

Several interesting researches into new methods of converting energy may come to fruition in the next decade The fuel cell promises to provide a method of converting chemical energy directly to electricity New electronic devices such as diodes filled with cæsium vapour or other plasma devices may provide a new method of converting heat to electricity to supplement our present methods The development of power by the fusion together of the light elements seems still to be in the research stage, and practical applications are somewhat far away Nevertheless, they do provide a clear goal and a tremendous challenge for the future

The contributions of chemical and biological research to industrial growth have, of course, been equally important to those of physical research We all know of the developments made possible by new fibres, new plastics, antibiotics, insecticides, selective weed-killers, etc We shall see some examples of this work during our visits this week

One of the important problems facing us to-day is whether the organization of applied research in Great Britain can be improved, and, in particular, whether Government help to industrial research can be improved in effectiveness

We have, I think, a good deal to learn from some American organizations who have a consistent record of success in developing new products by objective basic research followed by applied research and developments Some of our large industrial organizations have also been very successful in creating new products, but research activity is overwhelmingly concentrated in these large organizations There seems to be a critical size for creativity in industrial research

A recent inquiry by the Federation of British Industries showed that the total qualified research personnel in British industry has doubled over the past ten years while expenditure has probably quadrupled On the average about 10 per cent of this expenditure is devoted to basic objective research, 35 per cent to the development of existing processes, 35 per cent to new products and 20 per cent to general services The highest ratio of qualified research workers to total employees is in the specialist medium-sized pharmaceutical and electronic firms and is next highest in research-based industries such as chemicals and electrical engineering In traditional industries such as food, drink, building and textiles it is much lower

The Federation's inquiry shows that five-sixths of the projects undertaken have found commercial applications or are likely to do so—a remarkably high figure A large proportion of firms would expand their present research activity if adequate resources were available The main limitation on expansion is a lack of qualified research workers, and at present 13 per cent of their available posts are unfilled

The survey states that few small firms have any qualified men engaged on research or capable of applying it However, we can take some comfort from the address by Dr D W Hill to the Parliamentary and Scientific Committee on the work of the research associations which particularly help the smaller-scale firms Dr Hill calculated that, on a conservative estimate, the benefit to industry from the work of the research associations is now more than £100 million a year—a good return for an expenditure of £8 million a year The work of the Shirley Institute, which some of us will see, is a good example of this Apart from its direct contribution to the textile industry, the Shirley Institute, together with the British Iron and Steel Research Institute, was largely responsible for introducing operational research into industry The Wool Industry's Research Association invented the powerful tool of partition chromatography, the world-wide importance of which was recognized by the award of the Nobel Prize to the inventor The major problem in applying the work of the research associations seems to be in increasing the number of technically trained men in smaller-scale industry

From all this evidence, it is clear that our ten-year programme for doubling the output of scientists and engineers is well justified especially when we bear in mind the importance of getting a much higher proportion of scientists and engineers into managerial positions The shortage of highly qualified mathematicians, scientists, and technologists will be a major difficulty to the universities during their expansion of the next decade An Institute of Physics and Physical Society inquiry has shown that we will need to increase the input of physicists to university staffs by 2½ times if we are not to lower standards during the expansion At the present time we are losing too high a proportion of our best scientists to the United States—20 per cent of our PhD's in physics—and this proportion is likely to increase as the United States giant space-travel programme accelerates The best way to reduce this drain is to improve our research facilities at home There has been a welcome increase in the Department of Scientific and Industrial Research grants to universities for equipment and technicians during the past six years, and this has been very beneficial, but we need a further steadily continuing increase to match the growth of our research schools and the increasing complexity of research tools

Not only the physical and biological sciences need more support The Committee of Section N of the British Association which deals with sociology, social anthropology and social psychology reported that these three social sciences have suffered acutely from the lack of research funds to make it possible systematically to build up knowledge and valid generalizations in their sphere Grants from the United States foundations on which social sciences have relied rather heavily in the past are no longer as available as they were ten or fifteen years ago, since the United States foundations are directing their help increasingly towards the under-developed countries

These foundations argue, and justly so, that British social research should be financed to a far larger extent from British sources A more substantial provision of postgraduate scholarships is urgently needed, together with the complementary funds which would enable the students to undertake significant research Without assistance of this kind the Committee considers that it will be impossible to meet the demands for well-trained, responsible social research workers and university teachers

In considering our future investment in science, we have to take account of the increasing proportion of our funds for basic research which are going into international scientific organizations We have long been familiar with international conferences sponsored by the scientific unions and the International Council of Scientific Unions and with the International Geophysical Year, and other large-scale and world-wide activities The cost of these activities has been small relative to our overall scientific budget, and they have paid good dividends

We have now, however, reached the stage where several forms of science are becoming so expensive that only by international co-operation can smaller countries take part

The foundation of CERN, the European Council for Nuclear Research, devoted to the construction and operation of two large nuclear accelerators, at a capital cost of more than £15 million and an operating cost of £7–£8 million per annum, of which Britain pays a quarter, is a portent of things to come CERN has turned out to be extraordinarily successful both technically and scientifically, and has restored to Western Europe the possibility of working in the forefront of high-energy nuclear physics Physicists from Britain, France, Germany, Italy and other European countries now build in their own laboratories extremely expensive and complicated equipment such as liquid hydrogen filled bubble chambers, and move them to CERN where they are used by international teams This collaboration has been made possible by adequate Government grants for travel and assistance for university scientists We may, within two or three years, be faced with the problem as to whether to build a still more powerful nuclear accelerator at much greater cost to penetrate still deeper into the nuclear underworld If there turns out to be strong scientific reasons for this, it may need, for economic reasons, to be built as a combined United States–European project or even a world project

Space research is another expensive field of science and already collaboration between ourselves and the United States has enabled us to launch the first U K 1 satellite, using an American *Thor* rocket as a launcher Quite a number of experiments are proceeding well at the present time We are likely soon to see the coming into being of the European Space Research Organization, which may well have a budget three times as large as CERN We are therefore well within sight of spending about a quarter of our budget for basic research in international organizations We shall need to be very careful that, in periods of financial stringency, these investments do not reduce the funds available for basic research in our universities

We have so far been fortunate in not being tempted to enter the field of space travel, as distinct from space research The United States is already spending between 2 and 3 billion dollars a year on the programme of landing a man on the Moon, and the Russians are probably spending an equivalent sum According to *Izvestia*

> " a Russian-manned flight to the Moon will be followed by the establishment of a scientific station and ultimately by industrial-type installation Then will follow flights to Mars and Venus"

Although we can be excited by the prospect of landing on the Moon or Mars and collecting scientific information about their terrain and atmospheres and any evidence of life, there is no doubt that these ventures are being undertaken mainly for prestige reasons and as an instrument of power politics They may seriously distort the pattern of scientific development through the diversion of very large numbers of engineers and scientists to these objectives When we remember the statement of Paul Hoffmann, director of the United Nations Special Fund, that a contribution of 2 billion dollars a year to under-developed countries was required to increase the *per capita* income of these countries by 25 per cent in a decade, we must sadly conclude that world priorities have gone badly wrong

The final report of the Colonial Research Council reminded us that in recent years Britain spent about £2 million a year in supporting research in more than fifty establishments in Colonial Territories, mainly in the field of agriculture and medicine, and their contributions were great The need for continued help is clear if the battle against tropical diseases and tropical pests is to be overcome and agricultural production raised more rapidly than the increase of population—which is about 3 per cent per annum in African territories. The recent dissolution of the West African Intergovernmental Research Organization and reports of the exodus of professional workers show that the future is by no means clear

For all these reasons, we need to increase our investment in science just as rapidly as our human and financial resources permit Two years ago the United States President's Scientific Advisory Committee advised the President

> " . that simply in terms of economic interest our proper course is to increase our investment in science just as fast as we can to a limit not yet in sight"

The U S National Science Foundation now predicts that in their country investment in basic research in the universities alone will increase from 900 million dollars in 1962 to 2,700 million dollars in 1970 If we wish to maintain our position in the highly technological world of the future, we need to do as much and not only at least to double the proportion of our gross national product (now 0 2 per cent) devoted to basic research during the next decade, but to devote a much greater proportion of our applied research effort to furthering the development of new products and new industries and less to maintaining the position we held in the world of the past

The very great contributions which investment in science can make to human welfare in the future depend on achieving a reasonable degree of political stability in the world In his presidential address last year, Sir Wilfrid Le Gros Clark said that

> " the frightening question is beginning to present itself whether the civilization which mankind has slowly and laboriously built up over a period of many thousands of years can avoid disastrous dissolution as a result of uncontrollable struggles for political power or economic superiority and indeed whether the human species can avoid at least partial extinction by the misapplication of its own ingenuity"

The development during the past year of bombs which can destroy by heat alone everything within a radius of 20–30 miles below the point of burst has carried the world still further along the road to destruction

The dangers are so obvious and extreme that scientists and professional people who have special knowledge should make whatever contributions they can to solve the technical problems of the 'controlled and complete disarmament' which is now the declared objective of the United States, the U S S R and the British Commonwealth Soon after Sir Wilfrid spoke, an informal conference on Science and World Affairs met in Stowe, Vermont, and made some contributions to the solution of the most difficult of the technical problems—that of constructing an inspection system acceptable to both sides I hope that more can be achieved at the next conference, which is now in progress We must realize, however, that the great difficulties in achieving disarmament are political and not technical, and, if there was a real will on the part of all major powers to disarm, it could be achieved, releasing enormous resources for diversion to urgent needs of Britain and less-fortunate countries.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

LIGHTNING AND THE LONG ELECTRIC SPARK

SIR BASIL SCHONLAND'S presidential address to Section A (Mathematics and Physics) was preceded by an introductory film, made by Ferranti, Ltd , outlining the present knowledge of the generation and distribution of electricity in thunderclouds and describing the various processes in the lightning flash The typical flash to ground involves five separate processes an initial trigger discharge in the base of the cloud, a pilot and a following stepped leader lowering charge towards the ground, which, in the case of subsequent strokes or partial discharges, are replaced by single dart leaders, and finally in each case upward return processes starting when the leaders are close enough to some projecting object Interpretations of the detailed mechanisms of these processes are based on electric field and current measurements of high time resolution, on their velocities and on fast camera studies of their variation of luminosity with time

The most frequent value for the quantity of electricity carried down on a leader is 4 coulombs From recent measurements of the heights from which leaders start, the potential difference between cloud and ground can be re-evaluated as 10^8 V This provides only 350 V/cm as the potential gradient in the leader channel and leads to the conclusion that it has at its centre a narrow conducting core with arc characteristics This core is surrounded by a corona or ionization envelope of much larger diameter with glow characteristics At the front of the advancing channel the glow takes the form in virgin air of a controlled electron avalanche which is periodically caught up by the leader In subsequent dart leaders it makes use of pre-existing ionization

The breakdown processes in the long electric spark closely resemble those in lightning, and the step process has been identified in sparks in air, oil and water, on a scale 1,000 times smaller

Further investigations on sparks and lightning are required to provide fuller quantitative explanations of these phenomena on an atomic scale So far it can be deduced that there are two basic atomic processes governing breakdown in air—ionization, which sets a minimum electric field for advance (30,000 V/cm in air), and electron capture, which can only be avoided in the pilot channel behind the tip if the field there exceeds 4,000 V/cm The step process can be interpreted in terms of these fields

The radius of protection of Franklin's rod has now been explained quantitatively in terms of measured quantities in lightning leaders In the form of a horizontal earth-wire strung between the tops of power-line towers it is of crucial importance Recent unexpected failures in such protection, not necessarily involving interruption of electrical supply, but troublesome and connected with increasing heights of towers, require interpretation

An explanation of the occurrence of ball lightning in the Alps is offered in terms of two features special to this region The first is the recently discovered powerful ground flash of long duration from the tops of thunderclouds to mountain peaks, the second is the tendency of the ground currents supplying current to the return processes of such flashes to follow the beds of streams in Alpine regions of high rock resistivity Ball lightning may consist of bubbles of reactive gas occasionally produced by the heavy current in these stream-beds

CHEMISTRY OF TANNINS

PROF R D HAWORTH, in his presidential address to Section B (Chemistry), reviews the recent progress made in the elucidation of the chemical nature of vegetable tannin extracts which, until the advent of numerous modern techniques of isolation and analysis, has remained a difficult and therefore largely neglected field of study Although plant extracts may contain more than one type, vegetable tannins are classified as hydrolysable or condensed dependent on their action towards acids and enzymes The former group is conveniently sub-divided into gallotannins and ellagitannins, which give predominantly gallic acid and ellagic acid respectively on hydrolysis

The gallotannins, which are amorphous and probably mixtures of isomers and closely related substances, were originally investigated by Emil Fischer and have the general structure of polygalloyl carbohydrate derivatives, the carbohydrate is normally glucose, but several are now known, such as Tara tannin, which is a polygallolyquinic acid, in which the glucose is replaced by other carbohydrates or related substances The galloyl groups in the gallotannins are of two types, those linked directly to the carbohydrate and those linked depsidically to other galloyl groups, and although recent work has shown accurately how the former are distributed in Chinese, Sumach, Turkish and Tara gallotannins, the arrangement of the latter is probably random and remains unsolved

Closely related to the gallotannins are the ellagitannins, which are often crystalline, and elegant schemes for their derivation have been suggested. In general the ellagitannins are probably formed by oxidative coupling of adjacent galloyl groups on a simple galloyl glucose and the hexahydroxydiphenoyl group thus produced may then undergo modifications by oxidation, reduction and hydrolysis to give the many novel structures found in this group Compared with the state of knowledge of the structure of the hydrolysable tannins very little is yet known concerning that of the condensed or flavanoid tannins, which are amorphous and characterized by their conversion with acid to the insoluble highly coloured phlobaphenes They contain little if any glucose, but are thought to possess a common structural basis and to be derived by postmortal polymerization or polycondensation of the frequently occurring hydroxyflavan-3-ols and hydroxyflavan-3,4-diols Several dimeric products of these C_6–C_3–C_6 types have been isolated and characterized following acid-catalysed polymerization of the flavan-3-ol catechin, and these, it is suggested, are typical of the initial products formed in the complex process Other workers have suggested alternative oxidative pathways for the formation of these tannins, but this remains a field of study in which further work is clearly necessary

The developments made in the chemistry of the vegetable tannins concomitant with an increasing knowledge of the nature of the protein collagen chains in hide indicates the possibility in the near future of a greater insight into the chemical processes involved in the conversion, by the action of tannins, of animal skins into leather

PHYSICAL BACKGROUND OF BRITAIN IN THE PLEISTOCENE

THE "Physical Background of Britain in the Pleistocene Period" is described by Prof F W Shotton in his presidential address to Section C (Geology)

The fluctuations of climate in Britain during the Pleistocene may well have been more rapid than at any previous time in the country's geological history Associated with the waxing and waning of the glaciers must have been impressive shifts in the plant and animal populations, fed during the interglacials from the European mainland The argument is advanced that the Dover isthmus was established very early in the Pleistocene and thereafter remained unbreached until the well-authenticated cutting of the Straits about 7,000 years ago By contrast, it is suggested that there was no land link between Ireland and the rest of Britain until the last (Wurm) glaciation

There is much evidence available to the geologist by which he can evaluate climate It is almost certain that when the large ice sheets were established, dominant wind directions were greatly changed by this fact North-easterlies rather than south-westerlies would dominate Summers would be colder than now, but winters very much colder The very existence of glaciers down to the Bristol Channel and Essex demands a lowering of mean annual temperature in excess of 9° C, while the widespread frost structure soils (polygons, stripes, ice-wedges) entail a fall exceeding 7° C When these structure soils develop on a massive scale—polygons 20–100 ft across, stripes 20–50 ft apart—it can be assumed by analogy with the Arctic and Antarctic that 'permafrost' was present, that is, ground frozen winter and summer only a few feet below the surface One of the most spectacular features of air photography is the frequency with which corn crops, as they ripen in late July, pick out these large-scale patterns Other evidences of permafrost in Britain are pingoes, ice mounds, the dry valleys of limestone country and valley-bottom folds. There were certainly several separate episodes of permafrost and at each it may be argued that the mean temperature was depressed by 13° C or more.

A chemical method for evaluating temperature and humidity is provided by weathered soils (not common in Britain). In the Atlantic, Emiliani's work on the oxygen isotope ratios of foraminifera tests in deep sea cores suggests a damped down version of the more violent fluctuations on land, with an extreme variation of the annual mean of about 6° C.

The record of vegetational changes is of great importance and can be related to the physical conditions governing such features as the tree line, and the occurrence of the mixed oak forest. Some plants, like the holly and ivy, are indicators of winters which seldom went below freezing point.

Among vertebrate fossils, the musk ox, reindeer, arctic fox, lemming and a few others allow comparison with the arctic or sub-arctic, while hippopotamus and the fallow deer are equally indicative of mild conditions. Some extinct animals can now also be clearly related to cold or milder climatic conditions as well as to habitats, though exact estimations of climatic parameters are difficult.

The growing study of beetles is providing an ever-increasing number of opportunities of estimating climate as well as ecology. An assemblage of beetles can sometimes be placed closely within the series of plant zones which occur above and below the tree line, and these can again be translated into physical terms of temperature, particularly summer ones. In four English examples, all chosen from interstadials of the Last Glaciation and with ages ranging from 57,000 to 13,600 years, it is argued that the summer temperature was as little as 2½° and as much as 5½° below the present day.

FRONTIERS OF KNOWLEDGE IN THE STUDY OF SENSORY FUNCTION

In his review of recent progress in the field of comparative sensory physiology, Prof. O. Lowenstein, president of Section D (Zoology), deals with sense organs classified into three groups, according to the physical nature of the stimuli to which they respond. Electro-magnetic waves (light and radiant heat) are the appropriate stimuli for photo-receptors, mechanical deformation of parts of an animal's body are registered by mechano-receptors and chemoreceptors respond to changes in the chemical make-up of the external and internal 'environment' of the body. Up to fairly recently, sense physiologists were chiefly interested in exploring the range of sensory perception available to various animal types, and in an analysis of the range of functions of the various receptor organs. The focus of interest has now shifted to an analysis of the mode of function of sense organs on the cellular level. We are rapidly reaching a point where the ultimate understanding of the physicochemical processes involved in receptor function would have to be studied on a molecular level.

The chief topic of Prof. Lowenstein's address with reference to all three fields of receptor function is the question of transformation of the energy reaching the receptor organ in the form of its appropriate stimulus into the electrical energy of the final signal which is conveyed from the sense organ to the central nervous system in the form of propagated all-or-nothing action potentials.

All sense organs are incredibly sensitive. Their sensitivity thresholds lie in most cases near the limits of self-stimulation by molecular agitation. The energy content of stimuli at threshold is therefore minute. One quantum of light is sufficient to set up an excited state in a single visual rod in the retina of the mammalian eye. Such a rod presents a target of two thousand million photo-sensitive molecules of visual pigment to an incident light beam. A dent of half of a thousandth part of a millimetre in the nerve-ending of a tactile receptor and probably one molecule only of a scent are sufficient to set going the processes involved in the sensory perception of the stimulus. It is quite clear that the electrical signals which are generated by these stimuli and which are the carriers of coded information from sense organ to central nervous system have an energy content many powers of ten higher than the stimuli. A process of amplification must therefore be incorporated in the sensory mechanism.

One of the chief problems confronting the sense physiologist of to-day is to find out how an electromagnetic, mechanical or chemical stimulus is transformed into the electrical sensory message. This process of stimulus transduction can only be unravelled by an examination of the ultra-structure of the sensory cell and by a minute analysis of the physicochemical events going on in it.

The electron microscope has in recent years given us a chance to come to grips with this problem. The ultra-structure of visual cells, of sensory cells in the inner ear, of postural and chemo-sensitive receptors in vertebrates and insects, of the receptor cells in the mammalian nose and tongue has been investigated among others. A few tentative first steps have thus been taken in the elucidation of the fundamental receptor mechanism. Refined recording techniques based on the use of micro-electrodes and high-power biological amplifiers are being utilized in the attempt to analyse the mechanism of stimulus transduction. A few first victories in this offensive have been won and the fact has emerged that great fundamental similarities exist between the cellular processes in all the provinces of sensory function which have been studied by these methods. Exciting new information has also been gained in the field of the study of colour vision, especially in insects. Still great are the gaps in our understanding, and it has to be conceded that a real break-through will not happen until we are able to push forward the line of attack on to the molecular rather than cellular level of biological organization.

NUBIA: AN AFRICAN FRONTIER REGION

The building of President Nasser's High Dam makes Nubia of special interest to geographers.

First there are the physical effects of the Dam. Between November 1964 and November 1975, the Nile waters will rise by stages to some two hundred feet above maximum recorded levels, thus transforming the physical geography of Nubia. When the reservoir is full, a great lake will be formed, 300 miles long and 16 miles wide in places, bisected by the international frontier which divides Egyptian from

Sudanese Nubia This lake should not, however, be given two names—"Lake Nasser', for example, or "Lake Abboud" In memory of an ancient land and people, it should be called "Lake Nubia"

The High Dam is already beginning to disrupt the human ecology of Nubia, and the first of 100,000 Nubians are now being evacuated from their homeland Racially and linguistically, in their social organization and in their tribal traditions and beliefs, the Nubians, many of whom have lived for generations in comparative isolation, are a people of very ancient origins Much attention is being devoted to the ancient Egyptian monuments in Nubia, but little has been said or done about this human aspect of Nubian studies, about the need for research into the sociology and human ecology of modern Nubia The evacuation of the Nubians from their homeland, some to an environment as different as that of the Atbara River, is bound to result in some disintegration of the fabric and traditions of Nubian society Here a chance to study an ancient African community before dispersal has been missed

The High Dam also threatens to destroy an ancient cultural environment the geographical history of which forms the theme of Mr L P Kirwan's presidential address to Section E (Geography) The northern frontier of Nubia, racial and linguistic, lies in the neighbourhood of the First Cataract and is marked physically by the transition from limestone to sandstone and by the Pre-Cambrian rocks of the First of the Cataracts of the Nile The First Cataract was known to the ancient Egyptians and medieval Arab geographers as "The Gateway"—the gateway to the south It marks not only the northern boundary of Nubia but also the boundary between Near Eastern Egypt and an African frontier region leading to the Sudan

Nubia's traditional southern frontier lies near the Third Cataract This was the opinion of the Swiss traveller, John Lewis Burckhardt, the one hundred and fiftieth anniversary of whose first great Nubian journey falls this year Burckhardt, among many claims to fame, was the first, on this journey, to discover the Great Temple of Ramses II at Abu Simbel and five years later made the first excavations there in the drift sand then covering the temple He carried out his journey and these excavations on behalf of the African Association of London which was later absorbed into the Royal Geographical Society

Between these two frontiers, Nubia has been since about 2500 B C an almost rainless hilly desert region, with only a fringe of cultivation along the river The geographical value of the country can be summed up in terms of trade, mineral wealth, particularly gold, and the defensive advantages of Nubian terrain In ancient times, the shortest trade route linking the Mediterranean with Central Africa ran through Nubia, the key to it being the Third Cataract area from which trans-desert routes led to the Southern Sudan, cutting off a great bend in the Nile The Third Cataract area was reached by Egyptian explorers in the third millenium, among them Harkhuf, "the first explorer known by name in African history" Trading expeditions continued to use this route to the wealth of Central Africa in Graeco-Roman times One of these, launched by the Emperor Nero in the first century A D, reached to within some 500 miles of the Congo and Uganda borders, a feat of exploration unequalled until the nineteenth century

Nubia's principal mineral resources were stone, copper and, by far the most important, gold, the source of which was the rocks of the Basement Complex Possession of the gold deposits east of Lower Nubia induced the Pharaohs to occupy the country up to the Second Cataract about 2000 B C Four centuries later, gold, and the capture of the terminus of the trans-desert trade routes to the Central Sudan, were the motives behind the Egyptian colonization of Nubia, and of the Nile Valley between the Third and Fourth Cataracts

The key to defence in Nubia was the Second Cataract area This was Ancient Egypt's frontier for two centuries, and the disposition of the massive mud-brick forts there, now being excavated, shows how alive the Egyptians were to the advantages of Nubian terrain Conversely, in Graeco-Roman and in medieval times, the Second Cataract was the main line of defence for the Sudan

Valuable as Nubia was economically or as a defensive zone in ancient times, it was not then that she reached the zenith of her short-lived prosperity Even under the Pharaohs who have left so many monuments in Nubia, "the level of life, and of art, was never better than provincial" Much is now being written about Egyptian art in Nubia, but the Egyptian temples there owe more to the effects of an unusual and striking environment than to their qualities of sculpture or relief This is true even of the temples at Abu Simbel The Egyptian architects were very conscious of the need to relate architecture to environment Carved from the cliff-face of a sandstone plateau, "these massive memorials of arrogant, authoritarian power" are—in their present position—part of the geography of Nubia It is very doubtful whether they can ever be made to appear as their architects intended when they are lifted to their new position on the shores of "Lake Nubia"

It was not in Pharaonic but in Byzantine and medieval times that Nubia reached her zenith This was partly due to the introduction by the Romans of the ox-driven water-wheel which revolutionized agriculture and greatly increased the population It was also due to the importance of Nubia's geographical position in the strategy of the Byzantine emperors of the sixth century Nubia was brought within the orbit of the Empire through her conversion to Christianity in the middle of the sixth century by missionaries not from Christian Egypt but from Constantinople One of the most important and sensational discoveries made in Nubia in the past two years has been of a series of remarkable Christian wall-paintings at Faras in Sudanese Nubia These, discovered by an expedition sponsored by the Polish Academy of Sciences and the University of Warsaw, show strong Byzantine influence and confirm the direction from which Nubian Christianity came With them was discovered a memorial inscription in Greek which seems to commemorate the first Bishop of the Sudan

Christianity survived in Nubia until the fourteenth century, that is to say, for seven hundred years after the conquest of Egypt by Islam Early in the fifteenth century Nubia, following the invasion by the Ottoman Sultan Selim I, became nominally a frontier province of Egypt In fact, it was largely independent, a frontier zone, implacably hostile to all foreigners Even Napoleon's soldiers failed to enter Nubia, and it was not until Burckhardt's journey 150 years ago that a European succeeded in travelling the whole length of the Nubian Nile

ECONOMICS OF UNDER-DEVELOPED COUNTRIES

IN discussing the economics of under-developed countries before Section F (Economics), Mr W B Reddaway bases his presidential address largely on conditions in India, as analysed in his book *The Development of the Indian Economy*

There is no need for a different set of fundamental economic principles when studying under-developed countries, but the economic problems of these countries are normally different, at least in degree, and the background assumptions which one should make in studying any particular problem are also different These background assumptions do not correspond with those appropriate for analysing a Western economy on either of the traditional assumptions ('full employment' or 'recession')

The low level of output per head in under-developed countries is commonly attributed to lack of capital equipment and cultivable land, but much could be done by better methods of working to raise output per acre or per unit of capital These are usually better yardsticks of success than output per man

Nevertheless, it is most important to increase the stock of capital equipment of many kinds One great difficulty for under-developed countries is that most machinery must be imported unless there is a ready export market for things which they can easily produce, a development programme is likely to create an acute balance of payments problem, which cannot be overcome merely by willingness to save

Some useful capital assets, for example rural roads can, however, be created in the country by putting 'surplus' labour to work with simple tools and local materials, none of which presents supply problems Nevertheless, one cannot rely on the Keynesian multiplier process to generate the necessary savings to cover this expenditure the main secondary demand will be for food, the output of which is not limited by lack of demand A programme of additional investment in public works financed by credit creation would lead mainly to a balance of payments deficit or (if imports were controlled) to rising prices

The amount of rural road-making, etc , could, however, be expanded without curtailing other production if the expenditure were covered by taxation, or by aid from abroad in the form of surplus food-grains

An inflationary process is liable to be more rapid in an under-developed country because the profits which it generates do not typically accrue to companies (and so go largely into savings or tax provisions, with the remainder distributed later to shareholders), but rather to farmers and small traders, who may well spend them immediately

The development process renders the economy of a backward country very much more complex Each productive unit is more dependent on the proper functioning of many others, and on the marketing network Above all, the whole economy is dependent on the apparatus of Government, taken in the widest sense, attaining at least a certain standard of effectiveness

Developed countries can help by providing not only 'aid' (in the form both of loans, etc , and of technical assistance), but also trade facilities Admission of 'cheap Asiatic textiles' to their markets causes difficulties to particular producers, but these are as nothing compared with the problems which exclusion of such goods causes to the whole development of the poverty-stricken countries of Asia

TIME THE CATALYST : OR WHY WE SHOULD STUDY THE MATERIAL CULTURE OF PRIMITIVE PEOPLES

IN his presidential address to Section H (Anthropology), Mr Adrian Digby discusses this question

If we are to understand him properly, not only man but also his works should be the proper study of anthropology Thirty years ago this was recognized by the broad division between physical anthropology and cultural anthropology, which was itself divided into a major aspect, social anthropology, and a minor partner, material culture studies The common factor then was the primitive nature of the people to be studied But to have any practical utility, anthropology must extend its studies to more advanced societies, including our own, and to the reactions of these societies to new stimuli and to technological advance In pre-war days we regarded anthropology as, among other things, a convenient tool for the sympathetic and understanding administration of colonial peoples To-day, when more and more new nations are gaining their independence, and acquiring at a tremendous rate new technological processes and new political and social institutions from our own extremely complicated civilization, it is more important than ever to understand the effects of technological change on their social institutions, when we meet them as equals In particular the time taken in the new demands created by new techniques will have a profound effect on their social institutions

British social anthropologists, following the lead of Malinowski and of Radcliffe Brown, have concentrated intensively on the working of social institutions and their effect on the integration of society as a whole

These studies have not necessarily been limited to primitive communities, but are equally applicable to institutions in advanced communities The material and technological sides of man's activities seem to have been neglected, or in any event underestimated so far as their effects on social institutions are concerned

The historical approach to anthropology, exemplified in its extreme (and most unscientific) form by the writings of Elliot Smith and Parry, have been rejected as irrelevant

The students of material culture and primitive technology, tending to ignore social problems, and using techniques strictly comparable with those of the archæologists, have retained an evolutionary and historical approach, using the concept of diffusion, with caution, as a valuable historical tool Much of the work on material culture is relevant to archæologists if only by way of analogy and by the interpretation of the imperishable fragments of composite artefacts

But the relevance of technological studies to social anthropology, implied in the old term 'cultural anthropology', is relevant to modern social studies Social institutions must be influenced by the material needs of a community and by the time and labour involved in satisfying them Time and amount of labour will vary according to the techniques used

At a symposium of Section H in 1948 at Brighton, the effect of technique on social institutions was considered, but the conclusions suffered from lack of data on the time factor More recently McCarthy and McArthur made a careful study of the time occupied in the food quest by two groups of Australian aborigines, from which significant conclusions could be drawn Further, Manning Nash has recently published a study of pottery-making in a Mexican village in which he showed that the overall factor determining the output of pots was the incidence of fiestas He also drew general conclusions on the impediment to pottery-making caused by the presence in a family of young children and of the advantage held by families where there were enough women to introduce something akin to production line methods The value of these generalizations would have been enhanced if the time involved in the various processes of manufacture had been obtained

The method of timing operations will be difficult in large or complicated societies, but by careful sampling, combined with orthodox methods of anthropological research, valuable information should be obtained It is most important to obtain information on primitive techniques before it is too late

LIPID CO-FACTORS IN BIOCHEMISTRY

IN his presidential address to Section I (Physiology and Biochemistry), Prof R A Morton considers "Lipid Co-factors in Biochemistry"

Many enzymes have prosthetic groups, which may be detachable coenzymes These sometimes contain a water-soluble vitamin which is the locus of the substrate–coenzyme interaction

It is reasonable to postulate that fat-soluble vitamins may also act as co-factors in enzymatic processes The modes of action of lipid co-factors present difficult problems and progress has been relatively slow

The concept of a vitamin is now somewhat blurred Thus vitamin A has carotenoid precursors which in the animal organism yield vitamin A alcohol This is followed by ester formation and liver storage, and although the vitamin is mobilized as alcohol it may function as a derived compound Similarly, cholesterol is synthesized by the animal and dehydrogenated in the gut wall to yield provitamin D_3, which yields some cholecalciferol (vitamin D_3) under the action of ultra-violet light The status of vitamin D as a dietary essential is thus weakened although its efficacy under test conditions is not in doubt Vitamin E also has lost simplicity, the term tocopherol now refers to several natural substances varying in 'activity' The distribution of tocopherols in plant and animal tissues does little more than emphasize an antioxidant role

Vitamin K_1, with its phytyl side-chain, is found only in plant products and in fact has become somewhat elusive The numerous vitamins K_2 are 2-methyl-1,4-naphthoquinones with a polyisoprenoid side-chain at position 3 Vitamin $K_{2(20)}$ has a $C_{20}H_{33}$ side-chain and is peculiar to animals Vitamins $K_{2(30)}$, $K_{2(35)}$, $K_{2(40)}$, $K_{2(45)}$ are all found in micro-organisms Vitamin K-antagonists point to an enzymatic role and the lack of sharp specificity of chemical structure in relation to 'activity' raises difficult problems α-Lipoic acid leads to a useful linking of a fat-soluble co-factor with enzymatic processes catalysed by thiamine pyrophosphate

The blurring of the vitamin concept has been followed by the discovery of new endogenous lipid co-factors which are readily synthesized but which deserve to be called essential metabolites Thus plastoquinone (a 2,3-dimethyl-1,4-benzoquinone with a $C_{45}H_{73}$ side-chain at position 6) occurs in the chloroplasts of leaves and is perhaps more significant in photosynthesis than vitamin K_1 The alcohol solanesol ($C_{45}H_{73}OH$) occurs in plants and a cyclic isomeride of plastoquinone, solanachromene, is obtained from tobacco The ubiquinones are 5-methyl-2,3-dimethoxy-1,4-naphthoquinones with a polyisoprenoid side-chain $(C_5H_8)_n$-H, where *n* is 6–10

The compound ubichromenol (50) is isomeric with ubiquinone (50) and bears the same relationship to the latter as solanachromene does to solanesol

With regard to lipid co-factor functions real progress has been made, but baffling difficulties persist For example, retinene$_1$ (retinal or vitamin A aldehyde) is the key compound in vision, with special emphasis on one *cis*-isomer which combines with an amino group in a specific protein before a visual pigment can be formed Vitamin A acid (retinoic acid) can fulfil some of the systemic functions of vitamin A alcohol (retinol) but it cannot sustain vision, reproduction or some aspects of bone growth It may be that vitamin A alcohol is the precursor of a more powerful but very labile catalyst

The evidence on vitamin D suggests that in rats it tends to prevent rickets, when the causative low phosphate intake is marginal

Vitamin E occurs in animal tissues and its distribution in cell components does not exclude a major catalytic role, despite complicating evidence that synthetic anti-oxidants permit reproduction over three generations on a vitamin E-free diet The multiplicity of syndromes in different species and the response of some but not all, to catalytic amounts of selenite or organically bound selenium complicates an already difficult situation

The possibility that α-tocopherol, vitamin K and ubiquinone function in electron transport and oxidative phosphorylation has been much canvassed, and will be discussed by Dr F A Holton and Dr. E R Redfearn Plastoquinone is a key substance in photosynthesis and in photophosphorylation Vitamins K seem to function in plants and in many bacteria Some micro-organisms produce ubiquinones while others produce vitamins K, and a few produce both Tocopherols on oxidation yield quinones, and it seems that quinones may act as phosphate carriers via chromans or chromenes

Knowledge of the modes of action of lipid co-factors is in transition; most of the pieces of the puzzle are possibly to hand and bits of the picture are probably correctly assembled, but the major synthesis has still to be made The discovery of new quinones has transformed several topics and new techniques have radically altered the approach via enzymology and biosynthesis

IDENTIFICATION AND USE OF TALENT

TALENT in the sense of general mental efficiency, operational and latent, actual and potential, is identified and assessed by psychologists by means of tests This forms the theme of Mr Denis McMahon's presidential address to Section J (Psychology) These have certain advantages, but some scientific difficulties can arise which can lead to circular arguments From test evidence, which is backed by other evidence, it is clear that even before the 11-plus stage many able children have ‘opted out’ After 11, differences in performance in intelligence tests appear to reflect the goodness of the education and other environmental influences to a significant degree Home and social conditions affect even more markedly the ‘actual’ (as against the ‘expected’) school performance all the way through grammar schools and, in particular, the early leaving rate The social factors associated with these differences have now been identified It is now very clear that well before the university entrance stage a large proportion of the nation’s talent has dropped out—much of it sunk without a trace

It is complacently hoped that much of this talent is identified, trained and used in industry and commerce, Mr McMahon shows that there are no grounds whatever for such complacency

Individual variations of ‘vocational maturity’ are so great that all doors leading to careers should be left ajar as long as possible Examples are given of people “finding themselves” very late in their lives and, when given opportunities because of an open-door policy, making important contributions to the nation’s health, wealth, and happiness

Mr McMahon concludes with another aspect of developing latent talent and with an attempt to correct the tendency for the emergence of two nations in terms of culture and education A sketch plan is made of a scheme to use television programmes in the evenings in combination with tutoring provided by a local university—the aim and hope being the encouragement of an educated democracy

PLANT RESPIRATION AND MICRO-STRUCTURE OF PLANT CELLS

TO-DAY we realize that form and function are inseparable Organization is a convenient term to express the fusion of form and function, and the purpose of Prof W O James’s presidential address to Section K (Botany) is to consider that aspect of it which is represented by the respiratory–micro-structure continuum of plant cells

He describes respiration as covering the material changes undergone by complex cellular substances leading in the aggregate to a diminution of free energy and to an immense variety of intermediate products It can then be said that the structural unit associated with this function is the cell There are already known about fifty catalysed reactions which take some part in respiration, these reactions can be conveniently grouped under the headings mobilization, glycolysis, the pentose phosphate cycle and oxidation Both the energy and the materials which are the starting point for syntheses come overwhelmingly from aerobic oxidation, and so Prof James treats the oxidation stages as the core of his subject and the others as only ancillary to it

It is now without question that the mitochondria are the site of oxidations associated with the citrate cycle, but we have no great assurance that these are the only oxidations of significance to cell respiration

All living cells which have been examined contain mitochondria dispersed through the cytoplasm without any special orientation—in a lively cell to the number of probably several hundred They are often approximately spherical with a diameter of 0 5–1 0μ but are sometimes elongated or of more irregular shape The mitochondrion has a semi-permeable layered wall of lipoprotein which folds profusely into the central chamber which is occupied by an aqueous solution containing much soluble protein Mitochondria are extracted *en masse* by homogenization and differential centrifugation

The oxidations occurring in the mitochondria involve the following stages of electron transport besides others which are less clear

Substrate	e g Malic acid	Succinic acid
Dehydrogenase	Malic dehydrogenase	Succinic dehydrogenase
Dinucleotide	NAD (P)	
Flavoprotein	NAD-cytochrome *c* Reductase	Cytochrome *b*
Carriers	Cytochrome c_1 Cytochrome *c* Cytochrome *a*	
Oxidase	Cytochrome a_3 (P)	
Oxygen	O_2	

There are also further enzymes catalysing non-oxidative stages of the citrate cycle such as fumarase and aconitase and the kinases which catalyse the accompanying phosphorylations at (P)

Several lines of evidence indicate that cytochrome a_3 (cytochrome oxidase) is a firmly anchored constituent of the mitochondrial wall Moreover, the ability to oxidize succinic acid which is retained by broken mitochondrial walls indicates that the whole of the cytochrome system together with succinic dehydrogenase must be an integral part of the wall structure Further recent investigations in Prof James’s laboratory have failed to detect malic dehydrogenase in the sap, while of fumarase activity about one-quarter was in the sap and three-quarters in the wall It is therefore a reasonable guess that the entire enzyme outfit of the citrate-cycle and its associated electron transportation are a part of the membrane architecture There is also evidence that glutamic transaminase, which aminates the α-keto acids formed in the citrate cycle, is also included in the enzyme assembly of the mitochondrial wall It also appears probable that the soluble nucleotides NAD and NADP are firmly linked with their dehydrogenases on the membrane

The mitochondrion wall, like other cell membranes, probably consists of a lipid centre with protein layers on either side When the wall is disrupted, Dr Simon found with *Arum* mitochondria that the rate at which they would oxidize cytochrome *c* increased six-fold, probably on account of increase in the accessibility of cytochrome *c* to the internally sited cytochrome oxidase, but as six-to-one is a likely ratio for the internal surface/external surface of the infolded membrane we do not have to assume that the two surfaces have greatly different concentrations of the enzyme

We may reasonably suppose that the great bulk of the catalytic proteins are anchored to the inner surface of the lipid layer and we may think of the inner layer as possessing a mosaic of protein molecules cemented on to a lipid base In surface view the inner wall may be conceived as a repeating pattern of enzyme assemblies each containing all the enzymes necessary to put a succession of substrate molecules through the oxidation cycle and even to aminate some of its members, to transfer its lost electrons to oxygen and to phosphorylate ADP The internal surface of a moderate-sized mitochondrion could accommodate more than 100,000 such units

The enzymes of glycolysis and anaerobic respiration are highly soluble and do not appear to be attached to any particles so far recognized They are therefore supposed to be held in the ‘soluble cytoplasm , but it would be inadvisable to assume that the soluble cytoplasm is devoid of structure and electronmicrograms of cytoplasm *in situ* suggest that in many cells it may well be laced with an endoplasmic reticulum of membranes

While it would be premature to say that mitochondria are the only sites at which the production of transformable energy occurs, they are clearly the principal site of oxidative phosphorylation which provides the only mechanism of energy transfer in respiration that we know much about Neither chloroplasts nor ribosomes contain a respiratory oxidation system, nor do the nuclei appear to possess a normal oxidation equipment We have therefore the intriguing query whether the mitochondria can export their oxidatively accumulated energy to nuclei and ribosomes which appear to need it There certainly appears no reason why ATP regenerated by mitochondria should not be exportable, and experiments with nuclei and mitochondria isolated from the wheat germ have suggested that a sort of shuttle service ATP ⇌ ADP was being maintained by diffusion between mitochondria and nuclei, which used the ATP-bound energy to build peptide linkages

MARGINAL ASPECTS OF MODERN BRITISH FORESTRY

MR M V EDWARDS discusses the "Marginal Aspects of Modern British Forestry" in his presidential address to Section K (Forestry)

The practice of forestry in Britain, the forests and soils of which have been removed or altered by man, cannot be organized on the basis of methods devised in natural forests Afforestation has been planned for former woodlands and for grasslands, but difficulty has been experienced in fixing the limit to marginal land Experience has shown that greater success has been achieved if the site was modified and if exotic species were planted Recent Government policy changes emphasize a planned acreage programme concentrating on uplands and places where employment is deficient The re-assessment of afforestation limits on the basis of sustained volume of timber production and of manpower requirements is being made

The critical limiting factors are primarily climatic, of which precipitation (rain or snow), wind, and temperature are of first importance These must be known in general by regions, and also in particular for local areas and for micro-climates within the forest Soil factors of importance include the amount of soil available for rooting, its moisture balance and nutrient status, over the whole life of the forest All these factors have to be determined in relation to a range of different species of trees which are capable of establishment, and Britain is fortunate in having an extremely large number to work with

These factors result in a certain aspect of marginality over much of Britain's new forests Stresses between forest and habitat may be set up in Britain's new afforestation, and these have to be investigated as the forests develop The margins beyond which trees cannot be made to grow at all and those at which they can be established by modification of the site are gradually being supplanted by the marginal balance within the site and forest ecosystem

Problems are complicated by the long time-lapse which takes place between seed sowing and marketing of produce, and the difficulties of early determination of the qualities and quantities of mature produce It may also be difficult to determine the right scale by which to measure results, either as volume of timber or by alternatives such as dry weight or measures of quality Economic scales are difficult to apply in the absence of long-term data and they tend to operate against the use of degraded sites, the rehabilitation of which is one of the prime objects of afforestation The present scale of acres planted as used by the Government is a rough and ready approximation which should be replaced by a more definite appraisal of probable results

In natural forests the balance between habitat and crop has already been attained, but in artificial forests some form of human control is necessary Experience in forest nurseries has shown how artificial fertilizers can be used to replace organic manures, but only by maintaining a check on both the soil and the plant The same principles apply to forests Many possible future paths for progress in forestry now appear open, but probably the situation is in fact less unconstrained than it seems The future programme must be based on the investigation of the changes occurring in both habitat and crop as a result of new developments, and detailed recording of these changes is essential if undue risks are not to be run

THE UNITY OF KNOWLEDGE. A NEW DYNAMIC FOR THE SCHOOLS

MR PERCY WILSON begins his address to Section L (Education) with two quotations from Sir Julian Huxley's introduction to *The Humanist Frame* The first declares man's historic indebtedness to the arts and sciences, in all their variety and multiplicity, the second sketches Huxley's view of "evolutionary truth"—a process of enlightenment and liberation of mind to which, over a long process of time, we owe our culture, our security in life, so far as we have any, and our hopes for "the long future of our planet" These thoughts are linked briefly in the address with current fears about the fragmentation of the different branches of learning Mr Wilson's thesis is that, even at this late hour, the time is propitious for realizing Huxley's and Snow's hopes of a more united and dynamic national culture before the process of disintegration goes too far

These hopes—and their attendant problems—are then looked at in the schools, especially the fifth and sixth forms of the English grammar schools, where over-specialization is rife The mounting pressure needs to be relieved by an expansion and diversification of university education, by internal reforms in the schools and by modernizing the school curriculum This applies, for rather different reasons, to non-selective as well as to selective schools

Looked at from the wider perspective of the "Two Cultures", there are some alarming portents in contemporary culture These apply to arts and sciences alike, and examples are given from both sides But the most alarming is the arrogant mistrust of science and its contribution by those—and they are the majority of educated men—who are almost wholly ignorant of the physical sciences This ignorance cripples our understanding of the world we live in, as well as our ability to steer a rational course in our affairs

Apart from questions of internal administration, organization and curriculum in the schools and universities, there are important problems of the nature and inter-relation of the different disciplines

Some of these are examined, one by one in physical science, economics, history and literature Despite the growing narrowness of specialization, there is among the leading scholars and inventors more community of interest, more concern with mutual affinities, more attention to the junctions or interstices of the different subjects than there was fifty years ago This may be our last chance of an integrated culture, but it is probably our best for at least a hundred years "However the arts and sciences may differ in their methods and materials, they are only the dependent branches of the single tree of knowledge, and it takes more than one of them or even two or three of them, to make the tree comely and whole " It is for all school and university teachers to give their pupils some glimpse of the single tree of knowledge as this is seen by those great scientists, philosophers, poets, prophets and artists who have had, and still have, the synoptic view of learning

SCIENCE AND HUNGER

THE two basic facts of world hunger are first that half the present world population of 3,000 millions is hungry or malnourished, and, secondly, that the population is likely to increase to 6,000 millions by the year 2000, mostly in those areas where shortage of food is greatest Yet we could eliminate hunger and prevent its recurrence, if only we applied to the full the knowledge we already have With this as his basic text, Lord De La Warr summarizes the extent of this knowledge in his presidential address to Section M (Agriculture)

There is now a considerable amount of information about cultivation of soils, though much of it concerns temperate lands rather than the underdeveloped tropical lands Nevertheless, the soil conservationist, soil chemist, soil physicist, mechanical engineer and others are able to advise us both on soils and on irrigation The plant breeder can produce plants not only with greater yields, but also particularly adapted to special conditions, such as short or long growing seasons, drought and diseases and pests Herbicides and insecticides can greatly improve yields, which may be worth several times the cost of the treatment, they can also prevent loss during storage, which may amount to as much as 30 per cent of the harvest

Tools for cultivation can improve food production not only by making the labour force more effective but also by clearing, draining and preparing the land Mechanization need not be elaborate, for quite simple improvements can make a considerable contribution Our knowledge of animal nutrition allows far better yields of meat and milk In addition, we know now how to control many animal diseases, both nutritional and infectious Much infertility can be avoided, and animal genetics means that breeds can be improved so as to make them more suitable for a variety of environmental conditions

There is every possibility that fishing could be made to give us 50 per cent more food from the ocean, without danger of over-fishing It has also been shown that fish culture in fresh-water ponds can be a highly efficient way of producing food

It is important to remember that increased food production implies the simultaneous application of all these branches of knowledge Nevertheless, even if we produce enough food, we shall still find that there are many problems of ignorance and superstition which prevent proper nutrition

Thus the most important question which arises is how to put across this knowledge, especially in countries with low levels of training and education As with food production, the answer is again multiple Perhaps the first task is to ensure the training of indigenous advisers Farm institutes and agricultural and veterinary schools are necessary School gardens can be used not only for teaching how to grow food, but also for teaching what foods to grow for good nutrition Rural community development centres can also help, both in improving food production and in teaching nutrition In many parts of the world, co-operative farming, efficiently run, has been found to increase food production, and to make the best use of scarce materials, both human and mechanical Competitions between farms and communities, demonstration farms, and the use of modern techniques of instruction, have all proved useful methods of training

It is commonly believed that food surpluses in some countries could be used for relieving food shortages in others Such help can only be small in relation to needs, and in particular leaves the basic problem untouched, of improved food production where it is most needed Now that the scientists have given us the knowledge, it is up to Governments, educationists, and indeed all of us, to help rid the world of hunger and malnutrition

FACTS AND VALUES

THIS is the subject of Prof Morris Ginsberg's presidential address to Section N (Sociology)

The distinction between facts and values is often presented in the form of a sharp antithesis The philosophers tell us that from 'is' statements we cannot pass to 'ought' statements Social scientists in their turn say that they are concerned with means and not with ends, or that they can (with luck) tell us what we can do but not what we ought to do The impression frequently left is that values belong to a world of mystical intuition, or else have to be left in the end to individual choice or decision

The discussion of the issues thus raised has been greatly influenced by the work of Max Weber But his position is often misinterpreted He did not think that the value judgments implicit in our choices and preferences were incapable of being intelligently investigated On the contrary, it was of the greatest importance to bring out clearly the more remote ends and assumptions which they imply, to estimate the consequences, intended and unintended, likely to result from them and to consider the possibility of adopting new or different ends and assumptions He did not realize how closely this procedure resembles that advocated by those who believe in the possibility of a rational ethic In the end, his ethical outlook is sceptical and pessimistic It seems to be his view that when the process of analysis has been carried to its terminus, it would be seen that in the last resort values are incommensurable and irreconcilable No doubt he was led to this conclusion by the moral difficulties of power politics as he saw it in his own day The individual is left to choose between the demands of an "ethic of consequences" and the demands of an "ethic of ultimate ends" which has to be accepted or rejected in its entirety, presumably as a matter of faith Leaving this aside, as from a rationalist point of view unacceptable, it is important to inquire what bearing the sort of analysis outlined has on the problems of our own time, for example, on the differences dividing the communist world from the liberal-democracies It can be shown that as regards ultimate ends there is little or no disagreement The trouble is that the very loftiness of the ends removes them from the sphere of reality and opens the way to a dual morality, one for an ideal society the pattern of which is laid up in heaven and another in which what is called a realistic' policy is to be pursued regardless of moral standards Stripped of confusions arising from the intermingling of value judgments and judgments of fact the fundamental problem concerns the nature of the institutions most likely to curb the power of man over man and thus to make it possible to treat man as an end and not merely as a means There are signs that in recent decades the complexities of this problem are being increasingly realized in communist and non-communist countries alike and that, in this regard, we may expect that fuller knowledge of the relations between political and economic power and of the impact of modern technology on social relations may bring about some convergence of views now widely opposed or at least greater tolerations of divergence The problems involved are mainly factual, but the facts are distorted by implicit value judgments and these in their turn vitiated by an uncritical acceptance of supposed facts Indeed, it may well be that the problem is one for the psychology rather than the logic of morals From the philosophical point of view, the irreducibility of norms or values to facts is worth re-asserting in view of the persistence or revival of certain forms of legal or ethical positivism and, more particularly, of interpretations of Marxism which seek to justify communism by its supposed inevitability But this irreducibility does not mean that moral judgments have no basis in experience There is such a thing as moral experience Nor does the fact that there is an irreducible element in moral judgments make them mysterious there are irreducible elements in all knowledge

The practical difficulties of keeping questions of fact and questions of value distinct have been explored by the 'sociology of knowledge'—so far with very poor results There has been a tendency to assume that personal involvement or commitment necessarily distorts inquiry On the other hand, Marxist writers have urged that in social investigations we must give up the pretence of detachment and definitely take sides They thus make what might be called a pragmatic virtue of necessity As against both these views it is important to remember that detachment is a matter of degree, that in free societies bias does not remain undetected, and that, though a certain relativity of outlook is inevitable, it admits, in varying measure, of self-correction

ENGLISH AS AN INTERNATIONAL LANGUAGE

ENGLISH as an international language is discussed by Prof B Pattison in his presidential address to Section X (General)

Speech is an integral part of almost all human affairs, and languages develop and influence each other in response to their users' experience and contacts The novelty of the situation in the world at the present time is the density and range of communication Since the whole world is involved, there seems to be a need for a world language

Proposals for an artificial auxiliary language, to avoid invidious selection of the language of one community for general use, go back at least to the seventeenth century Recent ones have mainly been based on features common to a number of European languages The circumstances in which they were produced no longer apply with the emergence of new nations in Africa and Asia The solution of communication problems is being found by general use of a few natural languages of wide currency Of these English is the chief

The influence of the United States is one reason for the increasing use of English It has the technological expertise and the high standard of living most other nations want The English language has been the means of integrating people of diverse origins into one community It has endowed the Americans with the full European tradition The distinctively English contribution to that tradition was emphasized by the American War of Independence As a carrier of liberalism, English has struck deep roots in Asia and Africa

The strategic positions of English-speaking settlements have caused their lines of communication to encircle the globe Several European languages have established themselves on other continents, and French is as important as English in Africa But centres of English influence, such as those in south-east Asia, have tended in recent years to attract communities from other European languages Air lines have partly replaced shipping routes as carriers of English, and English is recognized as the international language of civil aviation

On attaining independence territories formerly governed by English-speaking powers are finding it difficult to change over to indigenous languages Many still need assistance from abroad, and English is the chief language of technical aid Education has been in English, which has given access to Western science and learning In many countries English is a force for national unity and a *lingua franca* of the educated from different speech communities It has lost its political associations and has been a working language for Afro-Asian conferences

There is no reason why any language should not eventually take over some of the present functions of English for local purposes, but it will take time for some to adapt themselves to new ways of thinking English itself took some centuries to become what it is to-day It is likely that by the time other languages have developed English will have established itself as the chief international language and will remain that Creolized forms of it, however, threaten mutual intelligibility among speakers of English from different parts of the world English-speaking countries have a great responsibility for helping to arrest a possible deterioration of standards of English which would deprive those to whom it is a second language of their present advantage in world affairs For historical reasons English has struck roots in many widely dispersed and diverse communities This explains its natural emergence as a world language and gives it an opportunity of providing a much-needed medium for international communication

THE MANCHESTER REGION

Manchester and its Region
(A Survey prepared for the British Association.) Pp. xviii+265+29 plates. (Manchester: The University Press, 1962. Published for the British Association.) 30*s*. net.

It can be said that the objectives of the annual meeting of the British Association for the Advancement of Science are essentially two-fold. The first is to present science in all its broadest fields to the world. The second is that the region in which the meeting is being held be given an opportunity to present itself. This second objective is made simpler if there is a means of gaining a preview of the area, and the more specialized knowledge gleaned at the addresses and excursions can be better appreciated. It was, in part, for this purpose that the survey *Manchester and its Region* was prepared. The result fulfils all in an admirable fashion and offers a most interesting and permanent record of Manchester up to 1962. The book of the survey consists of nineteen well-illustrated chapters prepared by thirty-three contributors, who are drawn mainly from the University of Manchester. There are also contributions from the Manchester Museum, the Civil Service and the Shirley Institute.

For the geographer visiting the region not only are the landscapes of 'Lancastria' ably described (the author here takes great care to define all technical terms used), but also excellent chapters have been prepared on the climate and the Manchester conurbation. Geologists are provided with a thirteen-page introduction to the area which is illustrated with bold maps styled after those presented by the Geological Survey of Great Britain in its *Regional Handbooks*. However, the authors of this chapter concentrate essentially on the geological history of the region, and, rather disappointingly, dismiss the 'structures' involved in just more than a page. For the botanist there is a chapter on "Interesting Features of the Local Vegetation and Flora", and here, on a very general ecological basis, the authors have chosen to describe only those features which they feel merit particular attention by the visitor. On the other hand, the fauna of the region is systematically described according to the various major classes represented. (An ample list of books for further reading is provided at the end of this chapter.)

Historians, including archæologists, are fortunate in that three chapters have been contributed. The first deals with Roman Manchester, the second with medieval and early modern Manchester, while the third covers "The Birth of Modern Manchester". Economists wishing to gain an insight into the structure of industry in Lancashire will find an interesting chapter which tackles such subjects as changes in population and the effects on industry, employment, the balance of industry and the location of growth industries. "Land Utilization and Agriculture in the North-West" describes such aspects as forest and woodland resources, urban development and other land uses, localized types of farming, the economic conditions of farming and the level of farm incomes. Those who take an interest in sociology will gain a good introduction from the chapter entitled "Social Statistics and Social Conditions of Greater Manchester". However, the authors are only able to deal in detail with the information that accrued from the *Census, England and Wales, 1951*, as only the preliminary results of the *Census* of 1961 have so far been issued.

Chapters 13–17 deal with the part that Manchester has played in the advancement of science, medicine, education (two chapters) and sociology, and this section of the book makes excellent general reading. For example, "The History of Science in Manchester" outlines the parts played in the rise of science and the Industrial Revolution by such scientists and engineers as Dalton, Frankland, Roscoe, Joule, Balfour Stewart, J. J. Thomson, Poynting, Rutherford, Schuster, Fairbairn, Whitworth, Osborne Reynolds, etc. This is indeed a formidable list on any account, and from this chapter one realizes the great debt that the world of science owes to such institutions as the Manchester Literary and Philosophical Society, Owens College, the Victoria University (of which the aforementioned was a constituent college) and the Manchester College of Science and Technology. The chapter dealing with Manchester's place in the history of medicine outlines the origins of the Medical School and systematically accounts for the work of such eminent people as White, Ferriar, Percival, Roberts, Whitehead, Jefferson, Dreschfeld, Barclay, Legge, Elliot Smith, Raper, etc., to mention but a few. This chapter deals with, as the author states, only those "who are no longer with us". Indeed, had the work of living medical men been included very much more space would have been required. The remaining three chapters of this 'section' are entitled, "Manchester and the Supply of Schools", "Adult Education in the Manchester Area" and "Some Social Pioneers".

The last two chapters of the book present the hopes for the future. Chapter 18 is entitled "The University of the Future", and Chapter 19 "Planning the City of the Future". These again make good general reading, but even more so for those who are participating in the 1962 Meeting of the British Association, who will be gaining much local knowledge and interest. Through this they will be equipped to judge for themselves the value of the development plans by which Manchester and its region can continue to play its part as one of the greatest industrial, commercial and cultural centres of the world.

The Local Committee who organized the survey and Prof. C. F. Carter, who edited the book, and his team of contributors are to be commended for the excellent way in which they have presented *Manchester and its Region*. So far as can be seen there are only two things that could possibly have improved it. The first is that not all chapters have lists of further recommended reading, and the second that a general index is not provided.

(*Continued from page 874*)

adding 2 volumes of cold ethanol, the precipitate is washed and redissolved in 0.2 M phosphate buffer *p*H 7.0. Alternatively, bentonite, prepared by the procedure of Fraenkel-Conrat *et al.*[5] is used instead of nickel ions. Preparations are titrated by the plaque technique described by Montagnier and Sanders[6]. When we repeated the experiment of Huppert and Sanders using these methods of preparing RNA, that prepared from the virus deposit was ten times as infective as that prepared from the supernatant (Table 1), the infectivity of the RNA preparations was abolished in 15 min at 37° C by 2 μg/ml. of ribonuclease. This experiment was repeated four times with the same result, which was not affected by the method of assay of infective RNA (Table 2). However, when the original method of extraction of Huppert and Sanders was substituted for the new method, the virus deposit again gave less infective RNA than the supernatant (Table 3). The loss of RNA titre in the deposit was thus due to the method used to prepare the RNA, and not to the infectivity assay.

Table 1

Sample	Infectivity of RNA prepared in the presence of nickel ions and assayed by plaque titration (p.f.u./ml. × 10³)			
Exp.	1	2	3	4
Tissue culture fluid	14	32	29	5
Supernatant 1 h at 100,000*g*	0.5	3	0.5	0
Sediment 1 h at 100,000*g*	11	41	22	1

Table 2

Sample	Infectivity of RNA prepared with nickel ions present p.f.u./ml. × 10³	Mouse LD_{50}/ml. × 10³
100,000*g* supernatant	0.5	1.0
100,000*g* sediment	6.0	5.0

Table 3

Sample	Infectivity of RNA (no nickel ions present during extraction) p.f.u. × 10³	Infectivity of RNA (nickel ions present during extraction) p.f.u. × 10³
Tissue culture fluid	60	43
100,000*g* supernatant	4	2
100,000*g* sediment	3	19

These results show that it is in fact possible to prepare infective RNA from EMC virus by extraction with cold phenol. Earlier[3], it was suggested that virus, unlike the 'infective RNA component', was resistant to the action of cold phenol by virtue of the protective protein capsid, but might be susceptible to the action of hot phenol as is ME virus[7]. Since infective RNA can now be obtained from virus using cold phenol, we looked for an increased yield of RNA infectivity with hot phenol, but found none, the susceptibility of both virus and infected cells to hot and cold phenol appears to be the same (Table 4). The reason for the original failure[1] to obtain infective material from the virus deposit was that the technique then used failed to inhibit traces of ribonuclease present in the final preparation, and that the enzyme destroyed the infectivity before it could be detected. That this may be so is shown in Table 3, where the main difference between the columns is the low infectivity of RNA prepared by the old technique from the centrifuge deposit. Preliminary results using the method described by Houck[8] showed that such deposits may contain more ribonuclease than the supernatants. Moreover, there was evidence that the tissue culture fluid and 100,000*g* supernatants contained an inhibitor of ribonuclease action which may protect the ribonucleic acid obtained from the virus in these preparations.

Table 4

Starting material	Infectivity of RNA obtained by cold phenol (4° C) extraction, nickel ions present during preparation PFU × 10³	Infectivity of RNA obtained by hot phenol (50° C) extraction, nickel ions present during preparation PFU × 10³
Cells 5 h after infection	23	13
Crude virus	12	4

Although there is now no evidence of a small 'ribonucleic acid component' in crude preparations of EMC virus it remains unlikely that virus is the only source of infective nucleic acid in infected cells. There is an eclipse phase during which the infectivity of extracted nucleic acid increases without a concomitant increase in virus titre[2], the maximum infectivity of RNA is reached about 3 h before maximum virus titre[2], and 5 μg/ml. of euflavin given at 4 h after infection suppresses the production of virus without affecting that of infective RNA[2]. However, our previous conclusions[3] as to the nature of the RNA component depended on the assumption that cold phenol extracts no infective RNA from virus, and may be incorrect.

POLYMERIZATION OF TRANSITION METAL β-DIKETONE CHELATES

By Dr. D. P. GRADDON

Department of Inorganic Chemistry, University of New South Wales, Sydney

THE determination by Bullen, Pauling, and Mason[1] of the crystal structure of *bis*-acetylacetonato-nickel(II) showed that this green, paramagnetic compound, long regarded as an example of tetrahedrally 4 co-ordinated nickel(II), was in fact trimeric, each nickel atom being octahedrally 6 co-ordinated(I). That this structure is preserved in non-donor solvents is implied by Cotton and Fackler's observations of the spectra and magnetic properties; they also suggest that at high temperatures equilibrium is established between trimeric and monomeric forms, and observe that only diamagnetic, presumably monomeric and planar, forms occur when bulky substituents obstruct polymerization[2,3].

The preservation of the trimeric form in hydrocarbon solutions is confirmed by our own observations of the molecular weight in benzene and of the equilibrium of the reaction with 2,6-dimethylpyridine in toluene[4]. Fackler[5], studying the equilibrium with pyridine, also found the anhydrous compound to be trimeric, though disagreeing with us on the nature of the intermediate addition compound formed. It

Figs. 1–3. Preservation of octahedral co-ordination in acetylacetonates: trimer (Fig. 1) of *bis*-acetylacetonato-nickel(II) and suggested dimer (Fig. 2) and polymer (Fig. 3) of *bis*-acetylacetonato-oxo-vanadium(IV). To avoid confusion only the donor oxygen atoms of the ligands are shown

should be pointed out, however, that the bases used were not the same, and it is quite possible that different bases lead to different intermediate products.

Since divalent transition metal cations generally show a co-ordination number six towards oxygen donors, it seemed likely that this form of polymerization might be a common feature of apparently 4-co-ordinated species, such as the anhydrous β-diketone chelates; the results of molecular weight determinations on *bis*-benzoylacetonato-nickel(II), *bis*-acetylacetonato-cobalt(II), *bis*-acetylacetonato-oxo-vanadium(IV) and *bis*-acetylacetonato-zinc(II) are reported here. From the experimental point of view these substances are difficult to examine because of excessive sensitivity to water, low solubility in non-donor solvents or, if spectroscopic methods are used, very small spectral shifts. Their molecular weights have therefore been determined by the cryoscopic method in a variety of solvents which are solids at room temperature; the results are summarized as follows.

(1) *Bis-benzoylacetonato-nickel(II)*. The green, anhydrous compound was obtained by azeotropic distillation of the dihydrate with toluene. Like the acetylacetonate it reacts with water, alcohols or heterocyclic bases to form *bis*-adducts. The mean molecular weights observed were 1,195 in triphenylmethane, 1,100 in naphthalene, 1,187 in diphenylamine, and 392 in camphor (theory for monomer 381, trimer 1,143). This compound is clearly trimeric in non-donor solvents, but monomeric in camphor, which presumably forms a *bis*-adduct; attempts to isolate the camphor adduct were unsuccessful.

(2) *Bis-acetylacetonato-cobalt(II)*. This was made anhydrous by the same method; apparently extremely soluble in toluene, it was obtained as a plum-red powder by slow evaporation of the solution over sulphuric acid. This, like the nickel(II) compounds, readily formed adducts with water, alcohols or heterocyclic bases. The mean molecular weights observed were 766 in triphenylmethane, 816 in diphenylamine, and 257 in camphor (theory for monomer 257, trimer 771). This compound is thus trimeric in non-donor solvents, though apparently not isomorphous with the nickel(II) compound in the solid state[6]. The vapour is reported to be monomeric[7].

(3) *Bis-acetylacetonato-oxo-vanadium (IV)*, $VO(C_5H_7O_2)_2$. This was prepared anhydrous by a standard method[8] and is known to form 6-co-ordinated adducts with heterocyclic bases[9]. Molecular weights observed were 523 in triphenylmethane, 546 in diphenyl, 510 in diphenylamine, and 247 in camphor (theory for monomer 265, dimer 530). This compound probably has the dimeric structure (II) in which the co-ordination number is raised to six by sharing oxygen atoms. It was noticeable that solutions in molten hydrocarbons, though at first homogeneous, slowly deposited a blue solid, possibly a 6-co-ordinated polymeric species (III).

(4) *Bis-acetylacetonato-zinc(II)*. Despite previous claims that the zinc compound is readily obtained anhydrous[7,10], it was found that the product obtained from the reaction of zinc oxide with acetylacetone, and crystallization from 95 per cent ethanol, was the monohydrate $Zn(C_5H_7O_2)_2.H_2O$. Lippert and Rutter[11] also obtained this hydrate and showed by X-ray analysis that it was monomeric and trigonal-bipyramidal, with the water molecule in an equatorial site. The hydrate was found to be soluble and monomeric in triphenylmethane (observed mol. wt. 280, theory 281.5) and on reaction with 4-methylpyridine gave 6-co-ordinated *bis*-(4-methylpyridine)-*bis*-acetylacetonato-zinc(II). The anhydrous compound, obtained by azeotropic distillation of the hydrate with toluene, was very hygroscopic; observed molecular weights were 285 in triphenylmethane, 275 in diphenyl and 281 in diphenylamine (theory for monomer 263.5). *Bis*-acetylacetonato-zinc(II) thus differs remarkably from the other transition metal β-diketonates examined in being monomeric (presumably tetrahedral) and in forming a monomeric 5-co-ordinated hydrate. There appears to be no evidence for a dihydrate, though 6-co-ordination occurs if a heterocyclic base is used as donor.

Since the lower co-ordination number of zinc(II) as compared with nickel(II), cobalt(II) and vanadium (IV) is clearly not attributable to steric factors, we conclude that the zinc ion is unable to tolerate so large an extent of transferred charge as the others; this is in accordance with the observed changes in the co-ordination number of zinc towards oxygen donors of various types[12] and with the ionization potentials of the respective atoms. The ability of *bis*-acetylacetonato-zinc to form a *bis*-adduct with 4-methyl pyridine, despite the strong donor properties of the base, must thus be attributed to the possibility of 'back co-ordination' from the full 3*d* shell of the zinc ion.

LETTERS TO THE EDITOR

ASTROPHYSICS

Microwave Spectrum of Saturn

RADIO observations of Saturn have been reported previously[1,2] at wave-lengths of the order of 3 cm Observations at longer wave-lengths, combined with these earlier observations, would define the microwave spectrum of the planet, thus making it possible to determine whether Saturn also exhibits the striking microwave phenomena presented by Jupiter, evidently as a result of a vast system of radiation belts[3,4]

To provide some knowledge of the Saturn spectrum, observations of the planet were made for a total of 85 h on 35 days during the period March 10–May 10, 1962 The telescope used was the 85-ft telescope of the National Radio Astronomy Observatory, equipped with a 10 0-cm travelling wave tube radiometer The observation, calibration, and data reduction procedures were identical to those used in a programme of Venus observations[5], and, in fact, the Saturn observations were taken concurrently with the Venus observations A mean disk equivalent black-body temperature T_{BB} was derived from each day's observations as with Venus Inspection of the values of T_{BB} obtained showed that they were distributed in the expected gaussian manner, with the exception of one extreme value which was discarded on the basis of Pierce's criterion[6] The mean value of T_{BB} from the set of reliable observations is

$$T_{BB} = 196 \pm 44 \text{ (m e) } ^\circ \text{K}$$

where we have assumed that the rings of Saturn do not contribute to the observed radio emission This assumption is very likely correct since the value $T_{BB} = 106 \pm 21^\circ$ K, found at 3 45 cm[1], is very close to the infra-red disk temperature of 125° K[7], strongly suggesting that the rings do not radiate at 3 cm Since the rings are known to consist of small solid particles, they can only radiate even less at longer wave-lengths Thus their contribution at 10 cm should be negligible The random errors in the data are too large to permit a search for temporal variations in the radio emission

Combining this result with the accurate 3 45-cm data of Cook *et al* [1], and assuming that the flux density S follows the law

$$S = Kf^x$$

where K is a constant, f is frequency, and x is assumed constant over the range 3–10 cm, we obtain

$$x = 1\ 40$$

This is the most probable value of x from the two sets of observations If we calculate the values of x that obtain if we apply the quoted errors in the most unfavourable way, we find that it is highly probable that the true value of x lies in the range

$$1\ 03 < x < 1\ 83, \qquad 3\ 45 \text{ cm} < \lambda < 10 \text{ cm}$$

Thus it is highly probable, but without great statistical certainty, that the spectrum is not that of a black body, with which $x = 2$ As a comparison, the value of x for Jupiter over the same wave-length region is very nearly 0 75

Despite the apparent departure from a black-body spectrum, a possible interpretation of the radio emissions at 3 and 10 cm is that both are entirely of thermal origin As has been noted by Sagan[8], the atmosphere of Saturn should create a strong greenhouse effect, which, with the presence of an approximate adiabatic atmospheric temperature gradient, will lead to a large increase in temperature with atmospheric depth Temperatures of the order of at least 200° K appear possible at some depth in the atmospheres of the major planets The difference in disk temperature at 3 and 10 cm then could be due simply to the fact that we look more deeply into the atmosphere at 10 than at 3 cm With this interpretation, the present results do not require the existence of a non-thermal source of radiation, and do not necessarily suggest the presence of radiation belts

A second interpretation may be made by assuming that we are observing atmospheric levels of the same temperature at 3 and 10 cm As mentioned previously, nearly all the radiation at 3 cm must be of thermal origin Then, with the present assumption, about 100° K of brightness temperature at 10 cm must also be of thermal origin The remaining 100° K of brightness temperature at 10 cm will then be of non-thermal origin But the brightness temperature of Jupiter at 10 cm is often of the order of 600° K[9,10], of which only about 200° might be thermal, leaving a non-thermal brightness temperature of roughly 400° K With these data, the non-thermal components of Saturn would have about 1/6 the intrinsic luminosity of the Jovian non-thermal component, taking into account the difference in planetary disk areas

The two alternate interpretations given here are based on the extremes in assumptions that are presently plausible, the true situation, barring presently unknown complications, must lie somewhere between the two possibilities Therefore, the absolute non-thermal radio luminosity of Saturn appears to be less than about 1/6 that of Jupiter, at centimetre wave-lengths, and may be, in fact, much smaller This is an expected result, since it has been widely surmised that the rings of Saturn will capture radiation belt particles very rapidly, preventing the existence of any dense radiation belt system Further elucidation of this point will require observations at longer wave-lengths, or with polarimeters, or with sufficient resolution to measure the extent of the source of radio emission All these are difficult because of the very low flux density received from the planet

I thank Miss Ellen Gundermann and Mr C E Heiles for carrying out the reduction of the observational data

10-cm Observations of Venus near Superior Conjunction

PREVIOUS extended observations[1] of Venus at 10-cm wave-length have given evidence for only a small variation in the mean disk equivalent black-body temperature T_{BB} with Venus phase angle i These observations were made during a period surrounding inferior conjunction, and did not extend to small phase angles Thus the disk temperature for small i could be inferred only from an uncomfortably large extrapolation of the uncertain function T_{BB} (i) derived from data containing significant random, and perhaps systematic, errors These circumstances have made it desirable to observe Venus, if possible. near superior conjunction This is difficult because Venus is then at maximum distance, leading to minimum signal-to-noise ratios, and the planet also appears close to the Sun, a powerful radiator which can contaminate the observations by introducing significant radiation into the antenna side-lobes

In an attempt to measure T_{BB} near superior conjunction, Venus was observed for 330 h on 44 days during the period March 9–May 13, 1962 The equipment used was the 85-ft telescope of the National Radio Astronomy Observatory and a 10 0-cm travelling wave tube radiometer[2] with digital data recording devices, this was the same equipment used to obtain the previous extended set of data[1] Observations consisted of 30-sec observations made with the antenna pointed directly at the planet, alternating with 30-sec observations made with the antenna pointed 30′ to one side of the planet These latter comparison positions were arranged symmetrically north, south, east, and west of the planet For purposes of calibration, observations of an argon noise tube were made at frequent intervals A directional coupler introduced the noise tube output power into the radiometer so as to avoid physical changes in the radiometer in the course of the observations The over-all telescope system was calibrated several times each day by observing the radio source 04$N$3$A$ in the same manner as Venus From these data, the ratio of the intensity of Venus to that of 04$N$3$A$ was calculated, which gives directly the Venus flux density, if the flux density from 04$N$3$A$ is known The adopted value of the 04$N$3$A$ flux density was 23 7 (10^{-26}) W/m^2/c/s[1,3] The standard black-body radiation formulæ and the ephemeris planetary semi-diameter then led directly to a value for T_{BB} An IBM 1620 computer, which read directly the punched-tape records prepared at the telescope, was used in the reductions These observation, calibration, and reduction procedures are identical to those used previously Thus the result obtained here is homogeneous with the previous data In particular, since the primary calibration standard is the flux from 04$N$3$A$, there should be no systematic differences in the calibration of T_{BB} between the present and previous sets of data

Inspection of the 44 daily mean values of T_{BB} showed that they were distributed in the expected random way about a mean value, except for (1) two values which deviated widely from the general run of values, (2) all data obtained during April 6–23, which deviated non-randomly from the mean by large amounts An analysis of these latter divergent data showed that values of T_{BB} based on observations using comparison points east and west of the planet differed significantly from the values obtained using north and south comparison points This can only be due to an interfering source of radiation, and the length of time over which this problem persisted shows that the source can be only the Sun Consequently, all points from this period were discarded The other two divergent points were discarded on the basis of Pierce's criterion[4] This left 36 of the original 44 days' observations, representing about 250 observing hours The mean value of T_{BB} obtained from these accepted data was·

$$T_{BB} = 610 \pm 55 \text{ (m e)}^\circ \text{ K}$$

The range of i spanned by the observations was $14^\circ < i < 37^\circ$, with the mean value of i being $i = 25^\circ$

The previous results gave $T_{BB} = 629 + 39 \cos(i{-}17^\circ)$ ° K for the range of i of concern here This relation predicts $T_{BB} = 660^\circ$ K at $i = 25^\circ$ Thus the present and previous results are mutually consistent They are strong evidence that the 10-cm phase effect is very small, nearly that given previously, and that there is little surface temperature difference between the illuminated and dark hemispheres of Venus

I thank Miss Ellen Gundermann and Mr C E Heiles for carrying out the data reductions

The Lyman-α Problem and the Geocoma Hypothesis

IN a recent review article, Donahue[1] has discussed the various hypotheses put forward to explain the observed Lyman-α radiation[2,3] in the night sky The observed radiation is apparently solar Lyman-α radiation scattered by neutral hydrogen There are three hypotheses concerning the location of the hydrogen namely, the interplanetary hypothesis[3]; the geocorona hypothesis[4,5] (origin in a thin, essentially spherical shell with multiple scattering important), and the geocoma hypothesis[6,7] (origin in a comet-like distribution at distances greater than some 5–10 R_E, single scattering important) It is felt that the review[1] is generally not unfavourable to the geocoma hypothesis, but several important points were raised by Donahue The purpose of this communication is to discuss briefly the general status of the geocoma hypothesis in the light of recent observational and theoretical evidence and, in particular, to discuss the problems noted by Donahue

The first question raised by Donahue concerns the needed density of neutral hydrogen and its distribution as reflected in the observed and computed isophotes The calculations of Thomas and Donahue[8] indicate that a spherically symmetrical geocoma has too much Lyman-α radiation at large zenith distances Thus, it appears necessary to take account of the asymmetry which was a part of the original geocoma hypothesis[6,7] Spherical symmetry is often assumed for simplicity and because of the lack of a suitable model The asymmetry arises because neutral hydrogen in the exosphere and outside the Earth's shadow is subject to radiation pressure and because neutral hydrogen outside the geomagnetic cut-off is moved in the anti-solar direction by the drag of the expanding interplanetary plasma Thus, we need a detailed knowledge of the Lyman-α flux, the configuration of the geomagnetic field boundary, and the velocity and density of the solar wind The geomagnetic field boundary may be quite important as it may extend to many tens of Earth radii on the night side[9] This fact clearly aids the asymmetry, and it should be noted that the asymmetry will tend to bring together the observed isophotes and the isophotes computed on the basis of the geocoma hypothesis[8] The fact that the geomagnetic field has an appreciable downwind extension favours the existence of neutral hydrogen in this location, this means that there probably will not be a deep minimum in the anti-solar direction on the geocoma hypothesis, as was anticipated by Donahue The calculations of the neutral hydrogen density in the exosphere are difficult as again there are many uncertainties The densities outside the geomagnetic cut-off are limited by the collision time-scale for charge exchange with the solar wind protons The current parameters for the solar wind have been used by Donahue[1] in a recalculation, roughly the correct amount of hydrogen is obtained, but the amount is perhaps a little too low The needed amount is well within the uncertainties, and the effects of the asymmetry (in particular, the appreciable downwind extension of the geomagnetic field) could well make up the difference Thus, there does not appear to be any serious difficulty with the observed quantities and the density distribution expected on the geocoma hypothesis

Donahue[1] also points out that the observed night sky Hα radiation turns out to be an argument against the geocoma hypothesis (that is, single scattering) instead of an argument for it as had been previously supposed[6,7] The Hα radiation observed originally[10] was thought to correspond to the Hα ($4\pi\mathscr{J}_{32} \approx 6R$) predicted by Brandt and Chamberlain[11] using preliminary values for the flux and width of Lyman-β

The Hα is found to be of galactic origin[18], hence, the lack of an atmospheric component of Hα could be used as an argument against the geocoma hypothesis If we assume the Lyman-β originates in the same portion of the solar atmosphere as Lyman-α, it comes from a region[12] with $T \approx 1 \times 10^{5}$° K and then has a full width at half-intensity of about 0 3 Å This width is 1/3 the width used originally[11] The latest measurements by Hinteregger[13] give a flux in Lyman-β some 17 times less than the value used originally Thus, the Hα intensity is some 3/17 ≈ 1/6 the value formerly found Since the effects of line broadening due to opacity or turbulence and the effects of a central reversal are to further reduce the intensity, we conclude that $4\pi\mathscr{J}_{32}$ (geocoma) $\lesssim 1\ R$ This is a very low value and indicates that the geocoma hypothesis is consistent with the Hα observations when more recent parameters concerning Lyman-β are used

There is now general agreement that virtually none of the night sky Lyman-α radiation comes from the interplanetary medium, its contribution[6,14] is certainly ≲ 1 per cent The theoretical calculations of Thomas and Donahue[8] taken together with the *Javelin No 3* observations[15–17] argue strongly against the geocoronal-multiple scattering hypothesis[1] I note, however, that some 20–30 per cent of the observed radiation could arise from the geocoronal hydrogen Since the problems concerning the geocoma hypothesis are not necessarily severe, it seems that the major portion of the observed night sky Lyman-α radiation should be considered as coming from the geocoma, this view is supported by the Doppler temperature of the radiation of 8,000–10,000° K[6,7,19], which implies velocities ≈ 12 km/sec

I thank Dr T M Donahue for correspondence concerning the night sky Lyman-α problem

PHYSICS

Conductivity of Photographic Emulsions

ATTEMPTS to explain the origin of the latent image in sensitive photographic layers often take into consideration the close conjunction of processes (electronic and ionic) present during the formation of the latent image with those concerning photoconductivity or luminescence in the same materials It is therefore possible to presume that a mutual connexion exists between the so-called photochemical sensitivity of the photographic layer on one hand and photoconductivity or luminescence on the other. This is so, because that part of the photoelectrons which will participate in the formation of the latent image[1] cannot take part in, for example, luminescence and at the same time will influence, depending on the sensitivity of the layer (that is, depending on the number and energy-levels of the active trapping centres for photoelectrons in silver halide crystals), the size and course of the growth of photoconductivity of a definite photographic layer Similar problems were investigated by Vacek[2], West and Carroll[3] and by Gross[4]

We have examined the connexion between the photochemical sensitivity and the course of the total conductivity (electronic and ionic) in the dark and under illumination for two types of photographic layers, namely, commercial light-sensitive materials and laboratory-prepared nuclear emulsions All materials were kept at 58 per cent relative humidity prior to measurement The measurement of conductivity was made by a direct-current method at room temperature Determinations of the light sensitivity was made by a method used for the determination of sensitivity to the total radiation effect in nuclear emulsions

From the measured curves we evaluated the ratio of the maximum values of conductivity in the dark (i_1) and at constant illumination (i_2) The sample was illuminated symmetrically between the electrodes by the sensitometric lamp of 450 W from a distance of 0 79 m All pairs of measurements were made on separate samples

Fig 1 shows the characteristic curves of those photographic layers and Table 1 gives conductivity measurements, which only shows typical cases from a series of measurements being presented

Table 1

Photographic material		i_1/i_2	Curve in Fig 1
Light-sensitive emulsion	Gradual-ortho *Foma* (17/10 *DIN*)	6	1
	Dia U Foma (3° Sch)	2 3	2
Nuclear emulsion	Sensitized with gold	3	3
	Unsensitized	0 8$_6$	4
Silver chloride single-crystal	Crystals prepared according to ref 5	0 4$_7$	

By comparing the values from Table 1 and the course of the characteristic curves in Fig 1 it is evident that for each type of photographic material (nuclear and light-sensitive emulsions) the higher sensitivity corresponds to higher value of the ratio between the total conductivity in the dark and under illumination This result can be quite easily explained The measured conductivity in the photographic layer at room temperature consists of electronic (or photoelectronic) and ionic (mainly interstitial silver ions) constituents The higher the sensitivity of the photographic layer the higher the concentration of the deep trapping centres in silver halide crystals, that is after illumination of the photographic layer most of the freed photoelectrons are trapped The trapped photoelectrons on the trapping centres attract interstitial silver ions and neutralize them $Ag_0^+ + e^- \rightarrow Ag_0$ Apart from that, part of the electrons are trapped on shallow trapping centres or may non-radiatively recombine with holes The conductivity under illumination is lower in comparison with conductivity in the dark, for the number of Ag^+ ions which can take part in the conductivity is lowered for above reasons

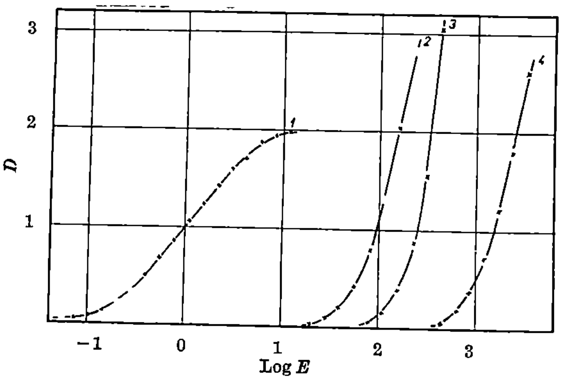

Fig 1

In materials of low sensitivity, where the concentration of trapping centres is much lower, most of the photoelectrons are not trapped This means that for a time they can take part in the conductivity (before they non-radiatively recombinate) and therefore the conductivity of the layer rises under illumination That is why the ratio of these materials is less than one

All these considerations confirm the measurements of conductivity made on single crystals of pure silver chloride, where the concentration of trapping centres in comparison with the photographic layer is a minimum That is why the ratio is smallest for these pure crystals (Table 1)

The conductivity measurement of a fogged photographic material ($D_0 > 3$) was also made The result of the measurement is interesting because the ratio was less than one in all cases

Transition Theory of Elastic-Plastic Deformation, Creep and Relaxation

The classical macroscopic treatment of problems in plasticity, creep and relaxation has to assume semi-empirical yield conditions like those of Tresca, Von Mises and creep-strain laws like those of Norton, Odqvist, Kachanov and others[1] This is a direct consequence of using linear strain measures, which neglect the non-linear transition region through which the yield occurs and the fact that creep and relaxation strains are never linear Tresca[2] pointed out that a transition state, which he called the mid-zone, existed, and Todhunter and Pearson have supported him[3] In this state the whole of the material participates, and not simply a line or selected region, as is assumed by classical theories Sir Lawrence Bragg[4] expresses this view when he points out that an element of a crystal, embedded in the matrix, should be pictured as being strained together with the whole mass of the metal, and hence the slip must take place by a whole intra-atomic distance A recent numerical investigation[5] on flow and deformation theories also shows that a continuous approximation through a transition state leads to a satisfactory convergent solution

A non-linear strain measure of the form[6]

$$s=(1-ne^{1/m})^{-1/n}, \quad m>0 \qquad (1)$$

includes a number of measures When $m=1$, we get the measures due to Cauchy, Green, Hencky, Alamansi and Swainger for values of n given by $n=-1, -2, 0, 2, 1$ No strain corresponds to $n \to \infty$ This measure readily gives the creep laws, both theoretical and experimental For example, Norton's law may be obtained by putting $m=1$, $s=\alpha t$ and differentiating the total strain s with respect to t, α being the average rate of creep-strain In like manner if we put $m=1$, $n=0$ (Hencky's measure) and $m=3$, $n=1$ in succession, and add the two rates obtained by differentiating $s=\alpha_1 t$ and $s=\alpha_2 t$ we get Andrade's very accurate experimental law[7]

$$l=l_0(1+\beta t^{1/3})e^{kt} \qquad (2)$$

This includes the transient creep flow represented by β and the ductile flow given by the exponential term Andrade's experiments show that this law holds good for a number of metals By using a functional in place of e in equation (1) we get Kachanov's law[8]

We may now satisfy the equation of equilibrium by using the measure in equation (1) and a quasi-linear stress-strain relation, which is found sufficient for most metals This avoids the use of complicated constitutive equations, which have remained mostly of theoretical interest Non-linear differential equations are obtained The concept of a transition state may be identified analytically with the asymptotic representation at the turning points of these differential equations Such representations have been used in a number of problems which involve quick transitions, discontinuities and non-uniformities[9] For elastic-plastic deformation the values $m=1$ and $n=2$ are found quite sufficient in equation (1) We get two turning points, which separate the regions of contraction and extension A number of other interesting results, which are generally assumed, come out of the equations and are now under publication[10] No yield condition is assumed It is contained in the solution

In like manner for creep rupture and relaxation the transition theory combined with the generalized measure (equation 1) does not require any yield condition or creep law[10] For a hollow tube subjected to internal pressure we get the same creep-stresses as obtained by Kachanov Results so far obtained suggest that the transition concept combined with that of a generalized strain measure can give a satisfactory basis for explaining a variety of irreversible phenomenon

GEOLOGY

Glacial History of Beerenberg, Jan Mayen Island

CERTAIN aspects concerning the glacial history of the Beerenberg mountain, described by F. J Fitch in a recent article[1], are in need of amplification and comment

In the original article the suggestion was made that the most recent minor re-advance of the Island's glaciers was probably near its climax This is the view of one of us (F J. F), and is based on the overall geological considerations regarding the moraine sequence on Jan Mayen, and not on any definite indications shown as yet by the glaciological and meteorological observations Undisputed evidence of a glacial surge was recorded during studies of Sorbreen in 1959 and 1961 This surge has very probably reached its climax The trend of increasing precipitation on Jan Mayen (with which can be associated the latest re-advance of the glaciers), is still continuing, and on this account it seems to the other authors (D J. J. K and J W S.) unreasonable to postulate that the post-1954 re-advance as a whole is near its climax. In other regions around the Norwegian and Greenland Seas a general fall in the level of precipitation has followed the trend of lower temperatures noticeable since about 1940 It will be of interest to see when the precipitation at Jan Mayen begins to fall off, if indeed this is going to occur

At Sorbreen, only three clearly defined modern moraine systems can be discerned, and by comparison with other North Atlantic areas these have been provisionally dated The outer series, by far the largest and best developed, probably date from about A D 1750 An inner, less well developed, series probably dates from the mid-nineteenth century (A D 1850–70) and the innermost, ice-cored series from about A D 1910–20 Certain other glaciers of the south-east and east coasts of Beerenberg (for example, Wardbreen, Fotherbybreen and Griegbreen) exhibit four distinct sets of modern lateral, and in the case of Wardbreen, terminal moraines In some cases these sets are themselves subdivided into a multiple ridge system Weak evidence of a four-fold concentric moraine sequence can be seen elsewhere (for example, at Smithbreen and at the ice-field margin by Ryggvarden), and it appears certain that a re-advance period, or periods, not easily recognizable at Sorbreen or Kerckhoffbreen, occurred at some time between the production of the large outer laterals and the smaller 1850–70 moraines The suggestion, made in the original article, that this re-advance occurred about A D 1810–20, must be regarded as only one of a number of possibilities until further comparative or absolute evidence is available More detailed descriptions of the glaciology of Jan Mayen will be published elsewhere[2–4]

The statement concerning the breaching of the crater rim of Beerenberg needs amplification There have been several suggestions as to the origin of this feature They fall into two categories (*a*) those which advocate a primary origin such as volcanic explosion or lava outflow, (*b*) those advocating a secondary origin, by erosion Even if the former is correct, the initial feature has undergone profound modification by subsequent glacial erosion The entrenching of the deep glacial valleys of the north coast has proceeded hand in hand with the breaching of the crater rim, and has extended over the period since the Joris Ice Advance[5] (2,500 years B P), when it can be shown that the glaciers occupied only shallow valleys

METALLURGY

Characteristics of Fatigue-activated Creep in an Aluminium–Magnesium Alloy

Experiments have been conducted on thin-walled tubes of an aluminium–magnesium alloy (3 08 per cent magnesium, 0 3 iron, 0 44 manganese, 0 18 silicon) under conditions of simple shear Two tubes aligned on a common axis are used for each test, the torque being applied through a disk connected to both tubes The assembly is mounted in a thermostatically controlled enclosure, and to avoid any possible errors due to inertial effects associated with the dynamic stress component, the torque is applied through a spring system A simple electrical device is used to maintain a constancy of torque (within 1 part in 5 × 10^3) as the disk rotates during creep The creep curves are recorded continuously by a photoelectric follower and associated recorder (a 'Graphispot') which traces the movement of a spot of light reflected from a mirror mounted on the shaft of the torque disk

Creep and creep recovery have been investigated with the equipment over ranges of stress and temperature In Fig 1, the continuous curves (which are accurately reproducible) represent the creep under a constant torque of 7 9 × 10^3 lb /in ^{2} at the temperatures indicated Similar sets of curves for creep-recovery have been obtained for clarity, only that for 160° C is here shown Recorded results of this kind enable critical comparisons with the theoretically predicted behaviour to be made In particular, the plastic component may be established by unloading after various creep-times (t_1, t_2,) and recording the residual strain (p_1, p_2,) remaining after a prolonged period of unload A plot of t against p represents the 'plastic' creep component such a curve for the case of creep at 160° C is shown in Fig 1 If the creep-time is long enough for the creep-rate of the anelastic, or recoverable, component to be negligible, then, on unloading, the form of the creep-recovery curve should be a reverse replica of the forward component (provided Boltzmann superposition applies) We can thus check the deductions directly by subtracting such a curve (that for 160° C is shown dashed in Fig 1, and marked 'recoverable component') from the total creep We find the plastic strain so deduced to be accurately in agreement with the curve derived by the first method Creep-recovery obeys an equation of the form $\varepsilon = k \log t$, and not $\varepsilon = k\,t^m$, and the values of k are linear with temperature above a critical temperature ($\sim$ 120° C in the present case) The plastic strain is linear with time except for the first few minutes, when a small transient (possibly best represented by $\varepsilon \sim t^m$, where $0 2 < m < 0 3$) is certainly evident The plastic component of the creep is strongly temperature dependent, and the rate increases critically above $\sim$ 140° C The linear rate of plastic creep, $\dot{\varepsilon}_p$, does not correspond with a single activation energy over the range studied, as will be evident from Fig 2, where the curve A demonstrates the temperature-dependence of this component This relationship should. of course, be given by a straight line if the simple rate-process equation is obeyed For the higher temperatures the slope yields an activation energy of 63 kcal /mole (which happens to be close to that for recrystallization in aluminium), while for the lower temperatures the energy derived is about 15 3 kcal /mole Clearly the temperature-dependence of the frequency factor in the rate equation cannot be ignored and detailed deductions from the data as they stand could be misleading

However, curve A (Fig. 2) can be used as a basis for comparing the creep under a superimposed fatigue stress Previous work[1] has, of course, demonstrated that both creep and recovery can be accelerated In the present experiments the alternating stress was applied electromagnetically, through the torque disk, at a frequency of 50 c /s The fatigue stress-level is about 1 per cent of the static stress (this can be estimated from the increased apparent width of the recorded light beam) The acceleration of the creep is evident from the dashed curves drawn in Fig 1 (the creep-rates for 170° C are so much greater (Fig 2), that they would require a much smaller scale drawing, are are not included here) Curve B (Fig 2) demonstrates the effect Rates are significantly increased above the critical temperature for plastic creep which for this stress is about 140° C The close parallelism of curves A and B suggests that no new process is being activated, but that the basic process (or processes) operative are merely accelerated The results are, then, consistent with those theories which regard fatigue-accelerated creep as resulting from an increased point defect concentration, and hence an increased rate of dislocation climb No new process need be postulated Whatever operations are

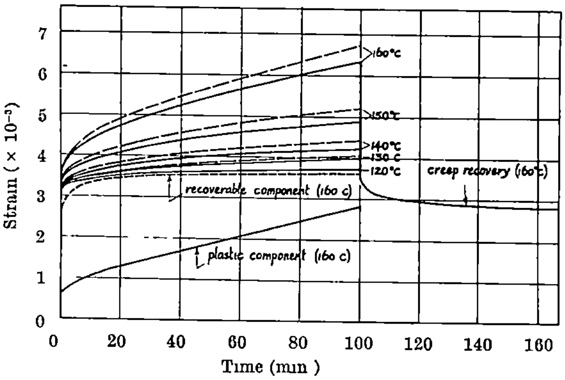

Fig 1 Creep curves of an aluminium–magnesium alloy under constant shear stress at the temperature indicated The dashed curves represent the creep when a fatigue stress with an amplitude of 1 per cent of the static stress is superimposed The creep recovery curve is shown for the case of the test at 110° C , and the analysis described enables the forward creep to be separated into the components drawn All the creep curves are continuously recorded

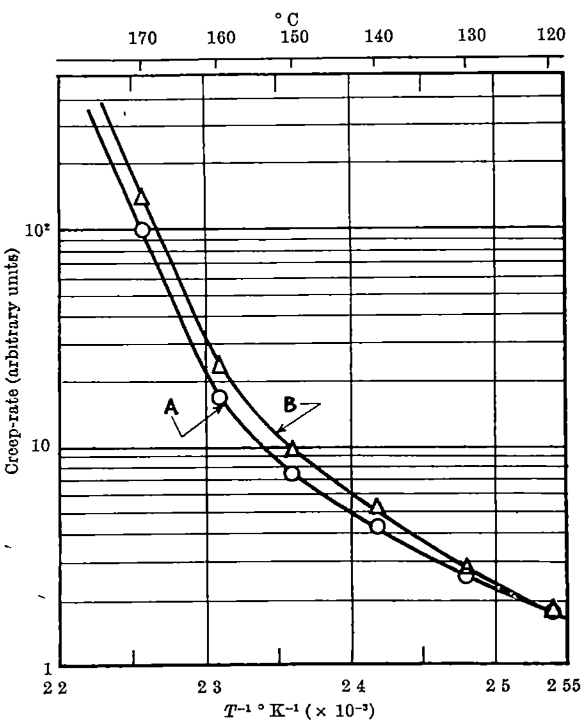

Fig 2 The logarithm of the steady-state plastic creep-rate plotted against the reciprocal of the absolute temperature for creep under a constant shear stress of 7 9 × 10^3 lb /in ^{2} (curve *A*), and also for creep under the same basic conditions, but with a 1 per cent fatigue stress superimposed (curve *B*)

carried out on the curves of Fig 2 to extract activation energies, the values would be the same for *A* or *B*

These investigations are being extended to alloys of special interest in connexion with the realization of a supersonic transport aircraft, as combined creep and fatigue conditions at skin temperatures in the region of 130° C will necessarily occur It is evident that relatively small-scale tests of this type can yield very definite information of significance to design The creep-rates imposed in the present experiments (10^{-4} hr $^{-1}$ at 140° C , for example) are higher than those acceptable, as an average, for the supersonic transport, but useful deductions can nevertheless be drawn about the nature of the effects to be expected, their characteristics and their possible importance

I thank Mr E W Wilson and Mr R C Whitbread, who carried out the experimental work, and the Department of Scientific and Industrial Research for a research grant

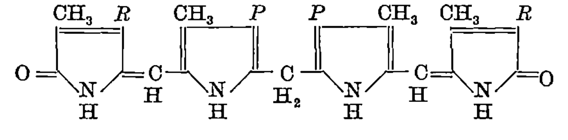
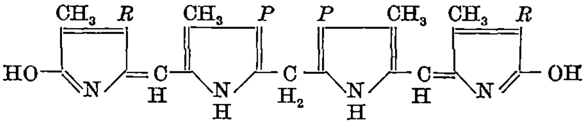
CHEMISTRY

Zinc Complex Salt Formation by Bilirubin and Mesobilirubin

ONE of the characteristic properties of most bile pigments is their ability to form complex salts with zinc ions, many of which display brilliant and distinctive fluorescence It seems to be generally accepted, however, that rubins do not form zinc complexes[1-4], mainly on the strength of Fischer's observation[3], that mesobilirubin gave no fluorescent zinc salt, and no further relevant work appears to have been published This belief has been used in support of the theory that the rubins exist in the *bis*lactam (I) rather than in the *bis*lactam form (II), as the latter contains two pyrrolenine nitrogen groups which should be capable of complexing with zinc ions, whereas the former does not[1,2,5,6]



(I)



(II)

$P = CH_2\ CH_2\ COOH$ Bilirubin $R = CH\ CH_2$
Mesobilirubin $R = CH_2\ CH_3$

I have recently obtained some evidence which indicates that bilirubin and mesobilirubin do form zinc complex salts

Bilirubin (10^{-5} M) in neutral 1 1 chloroform-methanol was yellow, with an absorption maximum at 452 mμ (Fig 1, curve 1) Addition of a drop of 2 per cent methanolic zinc acetate per 5 ml caused an immediate change of colour to saffron, the absorption maximum shifting to 476 mμ (curve 2) This solution was non-fluorescent under ultra-violet light When a drop of concentrated hydrochloric acid, or a few drops of glacial acetic acid were then added, the colour changed back to yellow, the absorption spectrum reverting to that of the pigment prior to the addition of the zinc acetate (λ_{max} 452 mμ)

Similar results were obtained in the case of mesobilirubin The absorption maximum of this pigment in 1 1 chloroform-methanol lay at 430 mμ (curve 3) On addition of a drop of 2 per cent zinc acetate in methanol, the absorption maximum shifted immedi-

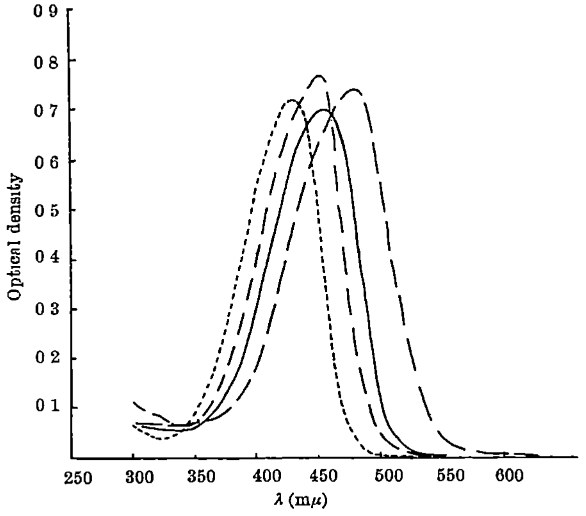


Fig 1 Absorption spectra ——— Bilirubin in 1 1 chloroform-methanol , — — —, same + zinc acetate , - - - - - , mesobilirubin in 1 1 chloroform-methanol , —— —— , same + zinc acetate

ately to 451 mμ (curve 4—solution non-fluorescent), and on subsequent addition of a drop of hydrochloric acid it reverted to 430 mμ In this case the spectral shifts were barely detectable visually

Since only acid-reversible reaction of the zinc ions with the rubins could be responsible for the foregoing spectral shifts (control experiments having shown that the acetate ions were not), this evidence indicates that bilirubin and mesobilirubin form non-fluorescent zinc complexes which, in common with the zinc complexes of other bile pigments, are readily decomposed by dilute acid, the original pigments being released

The zinc complexes of many bile pigments are oxidized rapidly on addition of a few drops of a solution of iodine in chloroform, whereas the free pigments are oxidized very much more slowly Iodine did not oxidize free bilirubin or mesobilirubin rapidly in chloroform-methanol solution, but on addition of a drop of zinc acetate in methanol, oxidation by iodine took place rapidly (giving mixtures of purpurins and choletelins) However, when zinc complex formation was prevented by addition of a drop of acid with the zinc acetate, rapid oxidation by iodine did not take place

This additional evidence seems to support the conclusion that the rubins form non-fluorescent complexes with zinc ions The structures of these complexes are being investigated

I thank Dr C Ó hEocha for his advice and for providing facilities for this work, which was supported by the U.S Air Force, through its European Office (contract No *AF* 61(052)–409) I also thank Prof C H Gray and Dr D C Nicholson for a sample of mesobilirubin

Acetone Isotherms

Casado, Massie and Whytlaw-Gray[1] measured the density of five organic vapours at 22° C with a quartz-fibre microbalance and obtained results which permit the calculation of second virial coefficients However, with acetone, the data imply a contribution over the experimental pressure range (26–136 mm) of a positive third virial coefficient sufficiently large to cause a two-fold change in the slope of the *PV*/*P* line, a finding quite at variance with Lambert's[2] linear isotherms Work on acetone by Pennington and Kobe[3] and Zaalishvilli and Kolysko[4] was conducted by methods which do not provide direct evidence on the *PV*/*P* curvature Recent *PVT* determinations at sub-atmospheric pressure for other organic compounds boiling near 50° C indicate that any supposed curvature is scarcely distinguishable from observational errors

To clarify the position we have recently examined acetone using the differential compressibility apparatus described previously[5] and offer a comparison with previous determinations (Table 1)

Table 1 SECOND VIRIAL COEFFICIENTS, CM^3/MOLE

	Present work	Lambert	Zaalishvilli	Pennington
50° C	−1,439	−1,560	−1,535	−1,480
22° C	−2,111	−1,960	—	−2,166

We have used $PV = nRT\ (1 + nB/V)$, Lambert and Zaalishvilli used $PV = nRT + nBP$, the final column is the value interpolated from the Stockmayer parameters given by Pennington and Kobe

Our technique, which permits measurement of the several *PV* products in one expansion to 1 in 10^5 shows that, as with other organic vapours similarly examined if there is any significant departure from linearity after the slight corrections applied for adsorption on mercury and glass surfaces, it is less than 2 or 3 parts in 10^5 for the pressure ranges examined (100 mm at 22° C, 200 mm at 50° C), at least ten-fold less than claimed previously, and favours a negative third virial Whytlaw-Gray's acetone results by the microbalance method, which is particularly sensitive to the purity of materials, decomposition of the acetone, and accidental contamination of the balance parts by minute particles of grease, we believe to be in error

To obtain further information about the general curvature of isotherms at reduced temperatures below 0 80, where the Stockmayer intermolecular potential indicates that the third virial coefficient becomes negative, it will be necessary to increase the available precision at least one order of magnitude In a very limited number of high-precision experiments, T_r = 0 5–0 7, recorded in the literature there is just an indication of such a curvature

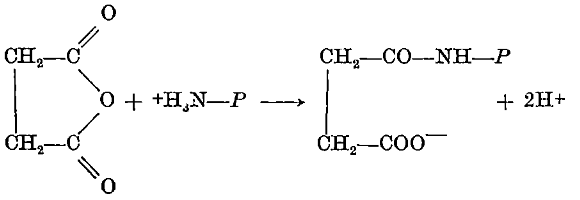
Dissociation of Proteins into Sub-units by Succinylation : Hæmerythrin

IN the course of investigation of the molecular weight of the marine oxygen-carrying pigment hæmerythrin (obtained from *Golfingia gouldii*), indications arose that the macromolecule of about 105,000 molecular weight might be constituted of several smaller units A few sedimentation experiments in solutions of sodium dodecyl sulphate, following a suggestion of Schachman[1], did reveal sub-units, but complete dissociation could not be obtained and the presence of detergent created a number of difficulties in experimental procedure Since the effectiveness of the detergent in splitting the macromolecule probably depends in part on the electrostatic repulsion produced by the large negative charge of the bound ions, it seemed worth while to examine the effect of the introduction of additional negative charges covalently linked to the macromolecule Reaction of protein with succinic anhydride[2,3] should replace each cationic ε-NH_3^+ charge by an anionic carboxylate group Since hæmerythrin contains about 80 lysine groups, complete succinylation would change the charge on the 105,000 molecular weight macromolecule at *p*H 7 by about 160 units



Succinylation was carried out very simply To the protein dissolved in dilute salt solution was added small quantities of solid succinic anhydride in small increments, the reaction mixture being stirred constantly The solution tended to become acidic as the reaction proceeded, the *p*H was maintained at 7–8 by the addition of dilute ammonium hydroxide

Samples were removed after the addition of various amounts of succinic anhydride and were examined in the ultracentrifuge The area of the *Schlieren* peak of the native macromolecule, with an S_{20} of about 6, decreased progressively and a new peak appeared with an S_{20} near 2 With increasing amounts of succinic anhydride, the fast peak was converted entirely into the slow one

To determine S^0_{20w} of the subunit accurately it was necessary to overcome any electrostatic effects on the sedimentation coefficient Sedimentations were carried out at high ionic strength, 0 2μ and 0 5μ borate buffers The sedimentation-rates in both buffers were identical, within experimental error, when corrected for differences in viscosity and density of the buffer solutions Thus charge effects are damped out at least at 0 2 ionic strength for this protein system Sedimentation coefficients were determined thereafter as a function of concentration and S^0_{20w} was found by extrapolation to zero concentration Combined with a measured diffusion coefficient, and with a partial specific volume assumed the same as that of the undissociated macromolecule, the sedimentation data led to a molecular weight of about 14,000 for the sub-unit Osmotic pressure measurements give 13,500 It seems clear therefore that hæmerythrin is composed of eight sub-units

Furthermore, it seems likely that other proteins composed of sub-units not linked covalently should be dissociable by succinylation The large negative charge thereby introduced is not a hindrance in characterizing the sub-unit by hydrodynamic measurements since the electrostatic repulsions can be damped out with aqueous electrolyte solutions of only moderately greater ionic strength than commonly used in analytical ultracentrifugation measurements

BIOPHYSICS

Conformation of Synthetic Polypeptide and Protein Monolayers at Interfaces

SYNTHETIC polypeptide monolayers at the air–water interface are generally thought to be in extended-chain conformations[1] though Bamford *et al* [2] have pointed out that the experimental data can often be interpreted as indicating the presence of the α-helix[3] Similarly, protein monolayers are usually considered to be denatured with the polypeptide chain fully extended[4]

To investigate the possible presence of the α-helix at the air–water interface, deuterium-exchange in N-deuterated synthetic polypeptide monolayers has been studied In solution peptide deuterium exchanges for hydrogen rapidly when the peptide groups hydrogen-bond to solvent molecules, but exchange is very slow when the polypeptide is in the α-helical conformation[5] Slow exchange in monolayers might similarly be an indication of the presence and stability of the α-helix The polymers used were poly-D-α-amino-*n*-butyric acid, poly-DL-leucine, poly-γ-methyl-L-glutamate, poly-γ-ethyl-L-glutamate and poly-γ-benzyl-L-glutamate, all prepared by Mr W E Hanby, of Courtaulds, Ltd , Maidenhead, to whom I am indebted All the polymers were spread from dilute solution in chloroform containing 8 per cent v/v O-deuterated dichloroacetic acid, with the exception of poly-DL-leucine, where benzene was used in place of chloroform

After being spread as monolayers on N/100 hydrochloric acid at 20° C for 10 min the films were swept off the surface, dried and examined by infrared spectroscopy The spectra in all cases showed very little deuterium-exchange and were typical of polypeptides in the α-helical form Exchange was observed in similar experiments using a substrate of N/100 sodium hydroxide though it was not always complete, and again the spectra were consistent with the presence of the α-helix A series of experiments with poly-γ-methyl-L-glutamate has shown that the exchange depends on the time the film is on the substrate and it is favoured by a high *p*H and temperature The spectra show that these same conditions also eventually lead to the formation of the extended β-conformation These results are all consistent with the general presence of the α-helix which becomes less stable on alkaline substrates so that ultimately the β-conformation may be produced

Measurements of the area per residue on a Langmuir trough supported this conclusion and agreed within 10 per cent of the areas calculated from the closest packing distances obtained by X-ray diffraction observations of the polymers in the α-helical form The surface potentials observed varied from 340 mV to 590 mV on the acid substrate and were somewhat less on the alkaline The α-helix can have no appreciable dipole-moment at right-angles to its axis unless the side-chains are polar and are arranged asymmetrically on the water surface If the conclusions presented here are correct this must mean that, at least for the polymers with hydrocarbon side-chains, the surface potential arises mainly from adsorption of water molecules on to the helix

Since the α-helix is probably the stable conformation of these polymers in a non-hydrogen-bonding environment, a further conclusion is that this will also be their probable conformation at the oil–water interface Doty[6] has shown that the helical content of proteins in solution is increased by decreasing the hydrogen-bonding capacity of the environment In the light of the results given here, this suggests that at least the regions of proteins where the side-chains are mainly hydrocarbon will be in a helical conformation at the lipid–water interface. Quite possibly the unfolding observed with proteins at interfaces is often a loss of the tertiary structure

The possibility that the α-helix is stable at the lipid–water interface is of considerable importance in relation to the biochemical activity of interfaces In contrast to extended chain conformations, the all-round arrangement of side-chains in relatively well-defined positions could lead to specific interactions with adjacent protein, with the components of the lipid and with the aqueous phase

BIOCHEMISTRY

Alkaline Phosphatase in Human Eccrine Sweat

In the course of histochemical investigations on the human eccrine sweat gland alkaline phosphatase reactivity in the luminal portion of the ampulla was observed[1] This observation has been repeated frequently, and it has been noted that this reactivity may continue into the proximal part of the coiled duct. Dr. G H. Findlay of Pretoria suggested that this phenomenon might represent deposition of alkaline phosphatase, if the enzyme were present in sweat We have found no reference to enable us to answer this question A random sample of sweat was accordingly collected from a normal male volunteer half an hour after the onset of profuse sweating in a 'hot box' It contained 2 9 King–Armstrong units of alkaline phosphatase

Further estimations were therefore made in the sweat of 5 normal adult males and one suffering from miliaria rubra ('prickly heat') The subjects performed light exercise under simulated tropical conditions (temp wet bulb 90° F ; dry bulb 93° F) and hourly sweat samples were collected from the interscapular region after washing with distilled water

Table 1 Alkaline Phosphatase Content of Sweat Samples in King–Armstrong Units

	Hours				
Subject	1	2	3	4	5
Ku	0 1	1 2	5 3	2 2	2 7
Mo	0 7	1 4	*	2 9	*
He	1 4	1 0	1 6	1 5	1 9
Be	3 2	1 4	2 4	2 1	1 3
Br	1 8	2 9	2 0	1 6	2 8
Na (miliaria)	5 0	0 8	1 6	6 1	10 6

*Insufficient sweat available

The method of estimating the levels of enzyme activity was that described by King and Wootton[2]

The source of this enzyme in sweat is presumably the secretory cells of the sweat coil, the cytoplasm of which shows marked acid and alkaline phosphomonoesterase activity We cannot say whether it is present in microsomal particles, as in milk[3] , if this were the case it might help to elucidate the mechanism of eccrine secretion Alternatively or additionally it could indicate increased permeability of the secretory cell membrane, analogous to that occurring in the kidney under experimental conditions[4] , the high figures obtained in a case of miliaria—a disease of the eccrine sweat unit—are of interest in this connexion and warrant further investigation

The work was performed with the aid of a grant from the Rand Mutual Assurance Co , Johannesburg, and is published with the permission of the Director of the South African Institute for Medical Research

Uridine Diphosphate Glucose-Glycogen Synthetase Activity in the Chick Embryo

In a recent paper[1], it was shown histochemically that glycogen synthesis began earlier than the appearance of phosphorylase in some tissues of the chick embryo In skeletal muscle, in particular, glycogen synthesis preceded the appearance of phosphorylase by about ten days[1,2] Because of that finding, it was suggested that the chick embryo, like the adult mammal, may be synthetizing glycogen through the uridine diphosphate glucose-glycogen (UDPG) pathway

In the investigation reported here fresh and frozen tissues of the chick embryos of white leghorn fowls were homogenized in sucrose and tested for the activity of UDPG-synthetase by the method of Leloir and Goldemberg[3]

The results indicate that in the heart, liver, skeletal muscle and brain UDPG-synthetase activity occurred earlier in development than phosphorylase and paralleled the appearance of glycogen in the tissues Fig 1 shows the activity of UDPG-synthetase in skeletal muscle of the chick embryo It can be seen that UDPG-synthetase activity was detected from the fourth day when glycogen synthesis was reported to begin[4,5], and about 10 days earlier than the date when phosphorylase was detectable histochemically[1] The evidence supports the theory that early glycogen metabolism of the embryo proceeds without insulin, for that hormone was not found in embryo pancreases until the 12th day[6]

These findings may help in the future understanding of such live and myopathic glycogen storages diseases which indicate the ability of these tissues to synthesize glycogen without being able to break down the carbohydrate

Zinc in Bone

The role of zinc in biological systems has been the subject of many investigations during recent years Addink[1] suggested a possible correlation between the zinc content of blood and liver and the presence of cancer No clear confirmation of this correlation has been obtained Zinc has been found to be an integral portion of several enzymes by Vallee[2] The high levels of zinc present in the prostate, in leucocytes and in sperm have been observed by a number of investigators[3] In general, the understanding of the role of zinc in biological systems is still largely reduced to a description of concentration differences rather than of metabolic interactions

In a recent article Taylor[4] infers that the zinc content of rat bone increases with age, for example, 77 p p m to 136 p p m to 200 p p m at 56, 313 and 679 days respectively If this is so, this finding would be quite useful in ageing studies and in the general understanding of bone structure. This suggestion prompted a re-examination of bones from several previous strontium studies for their zinc content

The stable zinc-levels were determined by means of an X-ray fluorescence method and confirmed by emission spectrographic analysis The satisfactory recovery of zinc under the conditions of ashing (12 h at 600° C) was verified using metabolically incorporated zinc-65

In Table 1 are shown the results from a group of Wistar-strain rats reared on a diet which had a constant zinc to calcium ratio of 2 75 mg zinc/g calcium This experiment was terminated at 414 days, as compared with the 679 days of Taylor's experiment No elevation of zinc in the bone was observed In fact, since the ends contain approximately 30 per cent more zinc than the shaft, one might expect that the femur zinc-level would go down with age as the ratio of compact to cancellous bone increases, if it should be expected to change at all

Table 1 Zinc Content of Rat Femur

Age (days)	Zinc (p p m of ash) Shaft	End	Femur
New-born	338	430	399
57	362	431	402
67	339	412	375
145	323	419	371
169	327	426	380
262	302	369	336
314	278	398	353
365	—	—	384
374	319	451	393
409	340	455	412
414	306	407	370
		Mean ± *S D*	380 ± 24

In Table 2 are shown data from human ribs selected at random from two sets of samples previously analysed for strontium[5] The results are tabulated according to increasing zinc-level in order to observe any possible correlation with age or locality. No such correlation is apparent, however, the six-fold increase in variance for the human samples, as compared with the rats on a controlled diet, suggests a definite correlation with the zinc and calcium ratio of the diet It seems likely that the level of zinc in bone is directly related to the zinc to calcium ratio of the diet, as was found to be the case for strontium. The inferred retention factor for zinc in rat bone would be 0 40 as compared with 0 28 for strontium

Effect of Phosphoric Acid on Digitalis Compounds

IT has been shown by Cox[1] that pregnane-3α,17α,-20α-triol (pregnanetriol) and related compounds react with 70 per cent ortho-phosphoric acid to produce a brilliant fluorescence Herman and Bruton[2,3] have shown that pregnanetriol and related compounds and digitalis compounds react intensely with antimony pentachloride, which thus can be used as a paper chromatographic detecting agent Since pregnanetriol reacts with both phosphoric acid and antimony pentachloride, by analogy, those steroids which react strongly with antimony pentachloride could be expected to react with 70 per cent ortho-phosphoric acid Heftmann *et al* [4] have noted briefly that aniline-phosphoric acid is useful as a detecting agent for cardiac glycosides

We have applied ortho-phosphoric acid to digitalis compounds and other steroids and have found that the natural fluorescence of the digitalis compounds under ultra-violet light is markedly enhanced Each steroid was dissolved in chloroform and applied to Whatman No 1 chromatogram paper in 50-μgm amounts or less The paper was dipped into 70 per cent orthophosphoric acid and placed on a sheet of tinfoil The paper was examined in visible and ultra-violet light (366 and 254 mμ) before and after heating at 80° C for 5 min

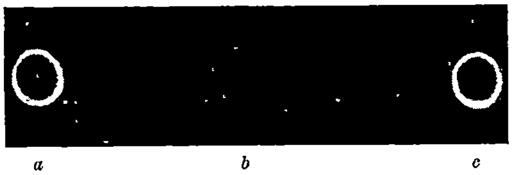

Fig 1 Fluorescent photograph of digitalis compounds treated with 70 per cent orthophosphoric acid The compounds are *a*, digitoxigenin, *b*, digoxin, *c*, digitoxin

Table 1 indicates the results obtained with digitalis compounds and other steroids and related compounds Fig 1 is a fluorescent photograph of the digitalis compounds treated with 70 per cent ortho-phosphoric acid The Whatman No 1 paper containing the treated digitalis compounds was placed on type *IF* contrast 5 Haloid photographic paper (Xerox Corp , Rochester, New York) and exposed for 5 sec at approximately 18 in using a 254 mμ ultra-violet light[5] Both digitoxin and digitoxigenin fluoresce with a bright yellow colour and are reproduced well on the Haloid photographic paper The digoxin fluoresces with a bright blue colour but appears much less intensely in the fluorescent photograph Haloid photographic paper is insensitive to wave-lengths of light beyond 450 mμ so that fluorescence at wave-lengths beyond 450 mμ can be recorded as an unexposed area

We were able to detect a minimum of 10 μgm of each of the three digitalis compounds in visible light using 70 per cent phosphoric acid With ultra-violet light (366 mμ) we could detect a minimum of 5-μgm with the fluorescence being more brilliant after heating

This technique should be useful as a detecting method for digitalis compounds

O-Methylation in Fish

DURING an investigation of the fate of some foreign organic compounds in fish, the metabolism of 3,4-dihydroxyphenylacetic acid (homoprotocatechuic acid) was investigated with the purpose of obtaining some information on methylation reactions in these animals DeEds *et al* [1] have noted that this compound is methylated at the 3-hydroxyl group in rats and rabbits A later report by Scheline *et al* [2] showed that homoprotocatechuic acid labelled with carbon-14 fed to rabbits at a dose-level of 100 mgm /kgm resulted in about 85 per cent of the radioactivity being excreted in the urine within 44 hr While the main excretory product was the original acid, nearly six per cent of the dose was found as 4-hydroxy-3-methoxyphenylacetic acid (homovanillic acid)

In the experiments described here 12 cod, *Gadus callarias*, weighing 420–1,370 gm (average 740 gm) were given homoprotocatechuic acid dissolved in saline The dose-levels ranged from 35 to 120 mgm / kgm (average 72 mgm /kgm) and the compound was injected intraperitoneally (nine animals) and intramuscularly (three animals) The method used for identifying metabolites was similar in part to that of Wood[3] and consisted of placing the treated fish in a small plastic tank containing 5 l of water The water was aerated and maintained at 10° C by keeping the tank in a constant flow of cold water After 20 hr the fish was removed, the water acidified, concentrated, and extracted with ether to obtain an extract suitable for chromatography Single dimension chromatograms of the extracts and reference compounds were made using three different solvent systems and the compounds visualized by spraying with solutions of brentamine fast blue *B* salt or 2,6-dichloroquinone chloroimide followed by 2 per cent sodium carbonate solution These chromatograms clearly showed the presence of 4-hydroxy-3-methoxyphenylacetic acid as well as homoprotocatechuic acid in the extracts While the relative amounts of these two substances varied somewhat from animal to animal, both were observed in all the experiments except one when, for an unknown reason, neither compound was found

Since the report by Axelrod[4] that the principal pathway in the inactivation of adrenaline and noradrenaline in man is one of *O*-methylation, considerable attention has been given to the subject of biological *O*-methylation The enzyme catechol *O*-methyl transferase which carries out this reaction is found in many mammalian species[5] and can methylate a wide variety of catechol compounds, including homoprotocatechuic acid[6] It has been noted that polyphenols such as pyrogallol inhibit the methylation of catecholamines[7,8] by acting as a competitive substrate for this enzyme[9]

Euler[10] has shown that visceral organs as well as chromaffin tissue of fish contain adrenaline and noradrenaline One might therefore expect catechol *O*-methyl transferase, or a similar enzyme system, to be present in these animals and for pyrogallol to inhibit the methylation of its catechol substrates With this in mind, six cod were given by intraperitoneal injection a solution containing both homoprotocatechuic acid and pyrogallol A dose-level of 40 mgm /kgm of homoprotocatechuic acid was used as this had been shown to give easily detectable amounts of the methylated metabolite The doses of pyrogallol were 40 mgm /kgm in two fish, 30 mgm /kgm in three fish, and 20 mgm /kgm in one fish and the extracts were prepared as before The results from these experiments clearly demonstrated that pyrogallol inhibited the methylation of homoprotocatechuic acid At the two higher dose-levels no 4-hydroxy-3-methoxyphenylacetic acid was observed on the chromatograms and only small amounts were found when 20 mgm /kgm of pyrogallol was given In all six experiments, the amounts of homoprotocatechuic acid on the chromatograms were increased over that usually seen

Also observed on these chromatograms was a spot differing in R_F value and colour reaction from pyrogallol or the methylated or dehydroxylated derivatives of homoprotocatechuic acid Archer *et al* [9] believe that pyrogallol first undergoes methylation on the 1-hydroxyl group before final methylation to form the 1,2-dimethyl ether The unknown compound differs from the 1-methyl ether of pyrogallol, however, in that its R_F value is slightly less and it gives a different colour after spraying with brentamine fast blue *B* salt In addition, it seems unlikely that it is the dimethyl ether as this compound would be expected to have a greater R_F value than pyrogallol monomethyl ether in the solvent systems used The identity of this compound is therefore not at present known although it is conceivable that it may be the 2-methyl ether of pyrogallol A similar reaction has been reported by Booth *et al* [11], who have shown that gallic acid is methylated to form 3,5-dihydroxy-4-methoxybenzoic acid

Carotenoid Pigments in Rotifera

THE Rotifera are remarkable among the Metazoa for their small size, often smaller than the largest ciliated Protozoa Many rotifers are colourless or at most show some slight colour in the gut wall, clearly due to pigment taken in with food A few species may have pigment spread throughout the body, others may have red eyespots and the fat globules of resting eggs may be bright orange in colour This combination of small size and general lack of colour makes investigation of the pigments of this group difficult and so far as we are aware no rotifer pigments have previously been identified

We have been fortunate in obtaining, more or less by accident, two species of rotifer in sufficient numbers to extract pigments from and apply chromatographic and spectrophotometric techniques

A dense population of *Philodina roseola* Ehrb was found in a dish in which the anostracan crustacean *Chirocephalus diaphanus* was being cultured The rotifers formed dense pink patches on the sides of the dish, and when these patches were scraped off with a clean scalpel they were found to consist of thousands of individuals of *P roseola*, together with even greater numbers of pink eggs intermingled with a few yeast cells which had been added as food for *Chirocephalus*

The food available to the rotifers was almost entirely yeast, but as the culture dish was placed near a window a few algal cells may also have been present There were no other species of rotifer in the material scraped from the dish and a few yeast cells would not interfere with the analysis since no carotenoid pigment is detectable in the bakers' yeast which we used[1]

Carotenoid pigments were extracted from *Philodina* in acetone and transferred to light petroleum (b p 40°–60° C) after dilution of the aceone with water The solution in light petroleum was washed with water to remove traces of acetone and dried over anhydrous sodium sulphate The absorption spectrum of this solution showed that a mixture of carotenoids was present The solution was poured on to an alumina column and the chromatogram developed by adding increasing amounts of acetone to the light petroleum used to wash the column Four fractions were separated

(1) A yellow fraction passed through the column with light petroleum and showed a maximum absorption at 449 mμ The position of this absorption maximum together with the chromatographic behaviour of the fraction is in agreement with the presence of β-carotene This fraction did not form more than 10 per cent of the total carotenoid pigments

(2) This fraction was eluted with 30 per cent acetone and showed a single absorption maximum in light petroleum at 468–470 mμ It formed about 35 per cent of the total pigment and appears to be an ester of astaxanthin

(3) A third fraction was eluted with 30 per cent acetone and came off the column after the astaxanthin ester The amount of pigment was too small to examine spectroscopically and formed less than 5 per cent of the total carotenoids

(4) The final fraction formed a deep orange band at the top of the column It was resistant to elution with acetone but moved rapidly down the column when a trace of glacial acetic acid was added to the acetone The pigment was taken into light petroleum, washed well to remove the acetic acid and acetone and dried over anhydrous sodium sulphate The pigment was hypophasic when partitioned between light petroleum and 90 per cent methanol even when the hypophase was further diluted, but on the addition of a drop of glacial acetic acid the pigment moved to the epiphase The absorption spectrum in light petroleum showed a single maximum at 468–470 mμ, which, coupled with the characteristic phase behaviour, indicates that the pigment is astacene derived from astaxanthin. This pigment formed about 50 per cent of the total, so together with the esterified fraction, astaxanthin formed about 85 per cent of the total carotenoids in *Philodina*

These results suggest that *Philodina* is able to accumulate carotenoids from food and convert these into astaxanthin. Observations on another rotifer, *Brachionus calyciflorus* Pallas, further support this suggestion This rotifer was collected in large numbers from the overflow water at the east end of the Long Water in Hampton Court Park The plankton sample consisted mainly of *B calyciflorus* together with a very few other rotifers and small crustaceans. The rotifers were separated from the crustaceans by making use of their reactions to light The rotifer sample was then placed in a Petri dish and warmed until the animals became immobile When the sample was examined under a binocular microscope it was found that only a very few other rotifers were present and counts showed the sample to contain 99 8 per cent *B calyciflorus*.

The carotenoid pigments were extracted from *Brachionus* in acetone The extract was much more dilute than from *Philodina* and so the absorption spectrum was measured in acetone before trying any further treatment Since the gut of these rotifers probably contained algal cells taken in as food, it was decided to compare the absorption curve of an acetone extract of *Brachionus* with that of a sample of phytoplankton taken from the Long Water on the same day as the rotifers were collected This would show whether the rotifers were accumulating carotenoids or whether the carotenoids in the rotifer extract were from algal cells in the gut These curves are shown in Fig 1 and it can be seen that they differ markedly in shape The curve from phytoplankton (Fig 1*a*) shows the absorption maximum of chlorophyll *a* at 432 mμ but in the curve from *Brachionus* (Fig 1*b*) this maximum has shifted to 414 mμ, suggesting that the chlorophyll has been converted to phæophytin *a* in the gut of the rotifers The curve from *Brachionus* also shows a region of maximal absorption over the range 450–480 mμ not present in the phytoplankton curve This is the result of the accumulation of carotenoids by the rotifers The shape of the curve from *Brachionus* suggests a mixture of carotenoids and this was confirmed by chromatography of the extract in light petroleum on a very small alumina column. Two bands of carotenoid separated on the column, a lower yellow band was eluted with 60 per cent acetone and an upper pink band was eluted with acetone to which a few drops of glacial acetic acid were added Too little of the pigments was obtained to examine their spectral properties but the behaviour of the upper band suggests the presence of astaxanthin.

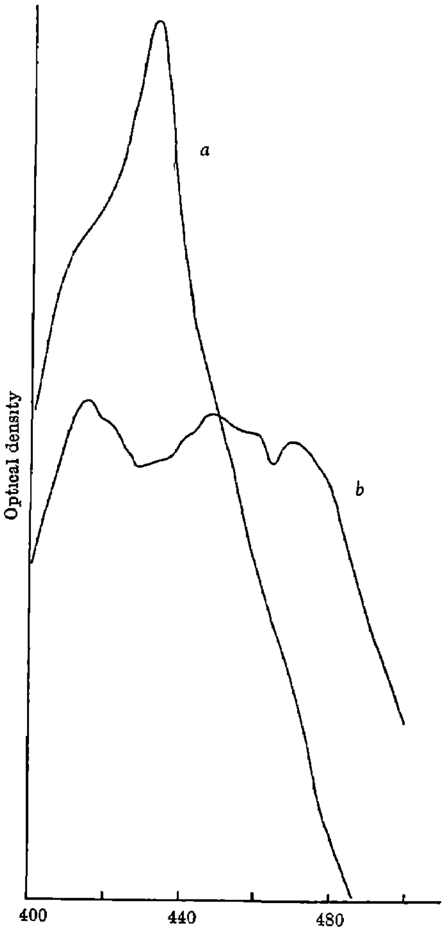

Fig 1 Spectral absorption curves of acetone extracts of (*a*) phytoplankton and (*b*) *Brachionus calyciflorus* from the Long Water, Hampton Court

An additional feature of interest in *Brachionus calyciflorus* is that the eggs are coloured pale blue and on treatment with acetone or dilute mineral acids they become pale orange This change in colour, coupled with the suggestion of astaxanthin on the alumina chromatogram, indicates that the eggs contain a carotenoprotein, thus showing remarkable similarity to the eggs of many Crustacea

These results add another phylum to those which include animals known to accumulate astaxanthin,.

and since *Philodina* belongs to the Bdelloidea and *Brachionus* to the Ploima, show that the ability to accumulate carotenoids is present in the two major subgroups of the Rotifera

A Solvent-soluble Fraction of the Fleece of Sheep associated with Suint

Suint has been defined as the water-soluble material in greasy wool[1], and recent work has shown it to be a complex mixture of salts of organic acids, polypeptide material, urea and colouring matter[2–4] The woolwax fraction in the fleece is usually determined by Soxhlet extraction with the appropriate solvent, but no importance has been attached to whether the Soxhlet extraction is carried out before, or after, the removal of suint[1] In addition, some workers have stated that the choice of solvents is not important, polar or non-polar solvents extracting about the same amount of material[5]

I have found that, with Romney cross-bred wools, quite different amounts of extract are obtained depending on whether wax determinations follow, or precede, suint determinations and in addition, differences between solvents are significant Table 1 gives typical results for some solvents, each result being the mean of six determinations made on wool from the same batch

Table 1 Results of Solvent Extractions

Solvent	Greasy wool		De-suinted wool*	
	Extract† (per cent)	C V (per cent)	Extract† (per cent)	C V. (per cent)
Petroleum ether 40/60	7 53	5 3	5 23	9 1
Diethyl ether	5 30	9 2	4 26	9 8
Benzene/methanol	10 88	5 1	5 22	8 7
Dry ethanol	8 65	6 1	5 94	11 5
Methylene chloride	8 28	5 2	4 35	10 3

* Suint removed by cold water
† Expressed as a percentage on clean oven-dry weight of wool

These results are not surprising when the heterogeneity of suint and wool wax is considered, and they are confirmed in recent work reported by Harker[6] They suggest that an 'overlap' material might exist, soluble or dispersible in water and also soluble in organic solvents Since other workers investigating the composition of suint have obtained their starting material after a preliminary solvent extraction of greasy wool[4,7–9], or by centrifuging and filtering the suint solution[1], it is possible that such an overlap fraction might have escaped isolation

Four lots of 50 gm of 50*s* quality greasy cross-bred fleece were gently stirred one after the other in 400 ml of cold water 200 ml of the resulting suint solution, after centrifuging to remove dirt, were evaporated to dryness and extracted with hot petroleum ether 40/60, yielding 290 mgm of a dark waxy material This possessed the unusual property of emulsifying spontaneously when shaken with cold water Table 2 shows its properties as gained from a preliminary investigation For comparison, the properties of the wool wax obtained from the same wool sample after removal of suint are also given

The material gave reactions similar to wool wax with the Liebermann–Burchardt and Salkowski tests, while micro-analysis revealed only a trace of nitrogen On the limited evidence available the material would appear to be a complex mixture of alcohols, a conclusion which is supported by its infra-red spectrum and high hydroxyl value

Table 2 Properties of Overlap Fraction and Wool Wax

	Overlap fraction	Wool wax from same wool sample
Colour	dark brown	pale yellow
Free fatty acid as oleic (per cent)	0	10
Slip point (°C)	42	40
Saponification value	60	91
Hydroxyl value	110	47

It is interesting to note that Anderson and Truter[10] have recently discussed the discoloration of wool wax recovered from both solvent and emulsion scouring in the presence of suint They ascribe this in part to the formation of an interfacial complex between wax and peptide components which darkens on heating The 'overlap' material described here could also be expected to contribute to a darkening of the recovered woolwax and like suint, would be removable by a cold water wash

I thank Dr E Corbett of the Department of Chemistry, University of Otago, for infra-red spectrographic analysis of the material

Soybean Phenoxyesterase

Esterases of blood plasma have been classified as *A*- and *B*-esterases on the basis of their responses to organophosphorous inhibitors[1] This classification has been extended to include esterases obtained from other animal tissues *A*-esterases (arylesterases) are not, whereas *B*-esterases (aliesterases) are, inhibited by organophosphorous chemicals Bergmann *et al* [2] isolated a *C*-esterase from hog kidney extracts which behaved like an *A*-esterase, but was activated by *p*-chloromercuribenzoate (PCMB) at concentrations which inhibited *A*-esterases Plant esterases have yet to be included in this classification An esterase from citrus[3] and wheat germ esterase[4] were originally described as acetylesterases Since inhibition was obtained with diisopropylfluorophosphate (DFP), they can be classified as acetyl-*B*-esterases

While we were characterizing plant enzymes which catalyse the hydrolysis of esters of phenoxyacetic acid, an enzyme which expressed considerable specificity for 2-naphthylphenoxyacetate (NPOA) was found in soybean seedlings This enzyme has properties different from those previously described Hence, the name phenoxyesterase is suggested

Acetone powders were prepared from the aboveground parts of 5-to-7-day-old soybean (*Glycine max* (L) Merr 'Lee') seedlings and extracted with cold

(3° C) distilled water The slurry was filtered through cheesecloth and the filtrate centrifuged at 12,000*g* for 15 min The supernatant constituted the crude enzyme preparation The *p*H of the supernatant was adjusted to 5 3 with 10 per cent acetic acid and the precipitate which formed was removed by centrifugation and discarded Alumina gel[5] was added to the supernatant at a ratio of 1 mgm gel/mgm protein After 30 min the gel was removed by centrifugation and the supernatant discarded The gel was washed with the original volume of cold distilled water and the enzyme was eluted with 0 01 *M* potassium phosphate buffer *p*H 7 0 Sufficient solid ammonium sulphate was then added to give 45 per cent saturation The precipitate was removed by centrifugation and suspended in 1/10 the original volume of 0 2 *M* potassium phosphate buffer *p*H 7 0 By means of the described procedure a 10-fold total purification, with 11 per cent recovery, was obtained when the enzyme was assayed with NPOA as substrate

The various 2-naphthyl esters used in this investigation were synthesized by the procedure of Gomori[6] Hydrolysis of 2-naphthyl esters was assayed by the method of Ramsey[7] 'Brij 35', a polyoxyethylene lauryl ether (Atlas Powder Co , Wilmington, Del) was used as an emulsifier at a concentration of 0 83 per cent (w/v)

The purified phenoxyesterase had an optimum *p*H of 6 0 (phosphate buffer) and the reaction followed first-order kinetics over the first 20 min During purification, enzymes which hydrolysed 2-naphthylacetate and 2-naphthylbutyrate were largely eliminated (Table 1) 2-Naphthylphenylacetate, -benzoate, and -caprylate and 1-naphthyl-*N*-methylcarbamate were not hydrolysed by the purified phenoxyesterase preparation Hence, phenoxyesterase hydrolyses neither esters of fatty acids nor esters of pure aromatic acids When the ethereal oxygen of phenoxyacetic acid is replaced by a methylene group as in 3-phenylpropionic acid, the corresponding 2-naphthyl ester was hydrolysed at a rate of only 0 7 per cent of that of NPOA Thus, phenoxyesterase shows a very high degree of specificity for NPOA

Table 1 RELATIVE ACTIVITIES OF CRUDE AND PURIFIED PREPARATIONS OF PHENOXYESTERASE ON DIFFERENT 2-NAPHTHYL SUBSTRATES AT *p*H 6 0 AND 37° C

Substrate	Relative activities Crude preparation	 Purified preparation
2-Naphthyl-		
phenoxyacetate	100	100
acetate	32	4
butyrate	19	3 6

Phenoxyesterase was inhibited slightly by 10^{-3} *M* copper sulphate (19 per cent) The enzyme could be protected against this inhibition by histidine, but not by glycine This behaviour suggests that an imidazole ring may be present at the active centre[2] PCMB had no effect on phenoxyesterase between 10^{-3} and 10^{-6} *M* Limited stimulation (17 per cent) was obtained with 10^{-3} *M* DFP This enzyme, therefore, appears to have properties different from *A*-, *B*-, and *C*-esterases[1,2]

Ethylphenoxyacetate (EPOA) was hydrolysed rapidly and at approximately the same rate as NPOA by both the crude and the purified preparations (Hydrolysis of EPOA was followed by an adaptation of the procedure of Hestrin[8]) Activity of the purified preparation was slightly inhibited (28 per cent) by 10^{-3} *M* DFP with EPOA as substrate Hence, an enzyme other than phenoxyesterase also possibly participated in the hydrolysis of EPOA

One of us (J v d W J) is grateful for support extended by the South African Wheat Industry Control Board and the South African Department of Agriculture Technical Services We thank Dr G C Klingman for help

PHYSIOLOGY

Effect of Hydrogen Ion on the Rates of Migration of Sodium and Potassium Ions

BECAUSE of its high mobility, H^+ is superior to other cations as a source of diffusion potentials From the differences between the mobilities of Na^+ and K^+ it could be anticipated that in the simultaneous diffusion of these three cations the effect of the diffusion potential of H^+ on the rates of migration of Na^+ and K^+ would not be equal As shown, for example, by Vinograd and McBain, the diffusion potential of H^+ has a distinct effect on the rate of migration of K^+ in the system of simultaneous diffusion of H^+ and K^+ [1] The effect of diffusion of H^+ on ionic distribution in the system of steady state has been examined by Teorell[2] The fact that little attention has been paid to the effect of H^+ on the selective migration of Na^+ and K^+ may be due to technical difficulties in the determination of these cations in the same fluid before the era of flame photometry

It was found in the present work that the rates of migration of Na^+ and K^+ are selectively changed depending on the direction of migration of H^+ in the diffusion system Furthermore, it was found that heparin selectively changes the rates of migration of Na^+ and K^+ and that this selectivity could be changed by simultaneous migration of H^+

A U-shaped diffusion cell (Fig 1) was first filled with 1 ml of the fluid into which the diffusion occurs Then 0 5 ml of the initial fluid of known concentrations of Na^+ and K^+ was carefully pipetted into the left limb After a diffusion time of 24 h at room temperature, 0 7 ml of the diffusate fluid was pipetted out from the right bulb and its concentrations of alkali metal ions was determined with a flame photometer The methodical error calculated from the 10 duplicate determinations was found to be 13 per cent for the diffusate Na^+ concentration, 12 5 per cent for the diffusate K^+ concentration, and 3 5 per cent for the diffusate K^+/Na^+ ratio The results in the tables are the means of triplicate experiments

The approximate potential difference between the initial fluid and the diffusate was measured by immersing calomel electrode KCl bridges in the fluids

Table 1 DIFFUSION OF Na^+ AND K^+ WITHOUT AND WITH SIMULTANEOUS DIFFUSION OF H^+

	Exp	Initial fluid (mM/l)		P d (mV)	Diffusate (mM/l)		
		Na^+	K^+		Na^+	K^+	K^+/Na^+
1	Diffusion of NaCl and KCl into water	100	10	+12	2 30	0 32	0 139
		50	50	+4	1 10	1 51	1 37
2	Diffusion of NaCl and KCl with 0 01 N HCl into water	50	50	−18	1 06	1 03	0 97
3	Diffusion of NaCl and KCl into 0 01 N HCl	50	50	+20	1 30	1 90	1 46

Table 2 DIFFUSION OF Na^+ AND K^+ FROM HEPARIN SOLUTION INTO WATER AND INTO 0 01 N HCl

	Exp	Initial fluid (mM/l)		P d (mV)	Diffusate (mM/l)		
		Na^+	K^+		Na^+	K^+	K^+/Na^+
1	Diffusion of NaCl and KCl from heparin solution into water	100	10	−34	0 75	0 065	0 087
2	Diffusion of NaCl and KCl from heparin solution into 0 01 N HCl	100	10	+4	1 30	0 18	0 138

in the two bulbs The potential difference between the electrodes (p d) was measured with a compensation potentiometer The symbol − or + indicates the sign of the charge of the initial fluid

In the first experiments (Table 1) the aqueous solution of sodium chloride and potassium chloride was diffused against water The second and third experiments (Table 1) show what happens when dilute hydrochloric acid diffuses in the same direction and against the direction of simultaneous diffusion of sodium chloride and potassium chloride Owing to the high mobility of H^+, the initial fluid was negatively charged when H^+ diffused in the same direction as Na^+, K^+, and Cl^- This decreased the rate of migration of both Na^+ and K^+ However, the migration of K^+ was retarded more than that of Na^+, resulting in a decrease in the diffusate K^+/Na^+ ratio Opposite changes were seen when sodium chloride and potassium chloride diffused against hydrochloric acid

Thus in the simultaneous diffusion of Na^+, K^+, H^+, Cl^-, and water, the relative concentration of K^+ with respect to that of Na^+ increased in the fluid having the higher concentration of H^+

It is obvious that the changes in the K^+/Na^+ ratio were temporary and dependent on the continuous migration of H^+ It appears that this condition is not far removed from what happens in the living cell H^+ is a metabolic product in the intracellular fluid Thus these results might be of interest in regard to the problem of selective accumulation of K^+ in preference to Na^+ in the intracellular fluid

It is generally believed that the selective distribution of alkali metal ions is the effect of a specific cation pump system in the cell membrane[3] The chemical basis of this hypothesis is imperfectly understood, however As pointed out by Ussing, other possibilities should also be considered[4]

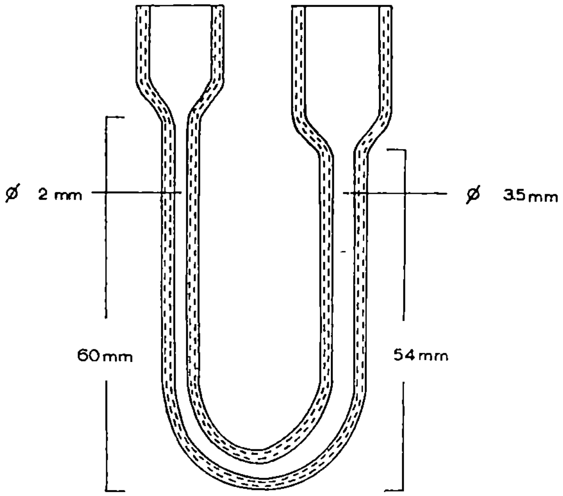

Fig 1 The diffusion cell made of 'Pyrex' glass

Ling, and Joseph *et al* suggested that negative charge of organic anions might be one of the primary reasons for the selective ionic distribution[5,6]. The present experiments with heparin solution are shown in Table 2 The composition of the initial heparin solution was as follows 100 mM/l of Na^+, 10 mM/l of K^+, 35 mM/l of Cl^-, and 2 4 g/100 ml of heparin Its *p*H was 7 3 (The original sodium heparin solution, 'Orion *OY*', Helsinki contained no K^+, and therefore potassium chloride was added to give a K^+ concentration of 10 mM/l)

Owing to the slow mobility of the heparin polyanion, the heparin solution was negatively charged when Na^+, K^+, and Cl^+ diffused from the heparin solution into the water The diffusate K^+/Na^+ ratio was lower than that of the heparin solution, suggesting that heparin acts as a cation exchanger immobilizing K^+ in preference to Na^+ This is in agreement with previous experiments carried out by the ultrafiltration through a semipermeable membrane[7] When the negative charge of the heparin solution was cancelled out by dilute hydrochloric acid diffusing against the heparin solution, the Na^+ and K^+ diffused from the heparin solution according to their free diffusion ratio, and the selectivity of heparin for alkali metal ions was thus abolished

Meyer and Bernfeld suggested that the origin of the resting potential of the intracellular fluid is the diffusion potential of H^+ diffusing out from the intracellular fluid[8] This hypothesis is not generally accepted The reason may be that it does not take into account the selective distribution of alkali metal ions It seems that this weakness in the hypothesis of Meyer and Bernfeld is partly overcome by the present finding, suggesting that the migration of H^+ may be one factor in the selective distribution of Na^+ and K^+

Temporal Summation of After-Hyperpolarization following a Motoneurone Spike

When recorded intracellularly, the soma-dendritic spike potential of cat spinal motoneurones (*SD* spike[1]) is followed by a brief phase of depolarization which reverses to a prolonged hyperpolarization (duration, 60–250 msec.)[1,2]. Investigation of after-hyperpolarization has yielded three experimental results which conjointly led to the hypothesis that it is due to a prolonged increase in permeability to potassium ions[3]: there is an increased membrane conductance, when the membrane potential is changed by applying current intracellularly, the size of the after-hyperpolarization is increased by depolarization and decreased by hyperpolarization, being reduced to zero at about 20-mV hyperpolarization, this equilibrium potential is shifted in the depolarizing direction by an electrophoretic injection of sodium ions into the motoneurone, which would of course result in a decrease of intracellular potassium ion concentration. In the present investigation on after-hyperpolarization, successive spike potentials of a cat motoneurone resulted in a considerable summation of after-hyperpolarizations and there was a corresponding increase in the membrane conductance.

Under 'Nembutal' anæsthesia the cat spinal cord was transected at the L_1 or L_2 segmental level. Single micro-electrodes were filled with 3*M* potassium chloride solution and inserted into motoneurones at the L_7 or S_1 level. The antidromic spike potential was induced in impaled motoneurones by a stimulation of cut ventral roots and also by passing a short depolarizing pulse (duration, 0.1–0.2 msec.) through an intracellular micro-electrode[4,5].

Rectangular currents of a small intensity (2×10^{-9} amp.) were applied intracellularly for monitoring the membrane conductance. The potential change in the membrane produced by the current was observed after the voltage drop across the electrode resistance was compensated for by inphase-rejection at the differential input stage of a d.c. amplifier[6]. These potentials were displayed on two beams of the cathode ray oscilloscope, one with a low d.c. amplification and the other with a high a.c. (t.c., 1 sec., Fig. 1 *A–D*) or a high d.c. amplification (*G–L*). The records in Fig. 1 *A–D*, *G–L* were formed by the superposition of about ten traces at a repetition-rate of 3 per sec.

In Fig. 1*A* the lower trace shows a spike potential in a motoneurone obtained by an antidromic stimulation, and the phase of the after-hyperpolarization is illustrated in the upper trace with a high amplification. In Fig. 1*B* a stimulating current pulse was applied through the microelectrode at an interval of 5.7 msec. after the antidromic stimulation and was adjusted critically so as to induce a small spike from the initial segment of the motoneurone, the *IS* spike[4,5], in about half the trials, as shown in the lower trace. It is seen in the upper trace of *B* that this direct pulse, and the thereby induced *IS* spike, did not make any appreciable change in the after-hyperpolarization following the antidromic spike.

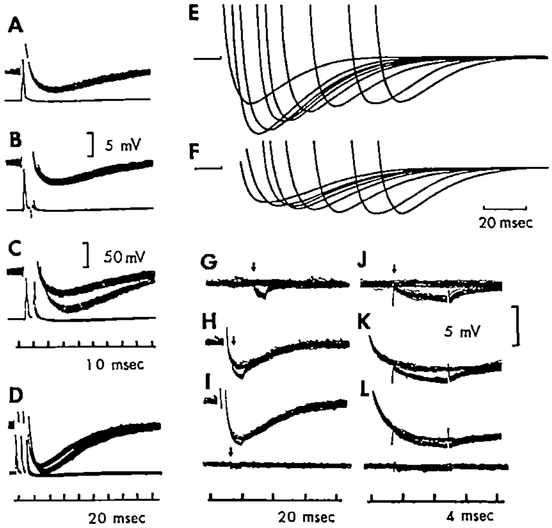

Fig. 1. *A–D*, antidromic spike of a cat motoneurone was followed by single (*B*, *C*) or double (*D*) intracellular stimulation. Voltage calibration of 5 mV applies to the upper traces and that of 50 mV to the lower ones. Time-scale of 10 msec. is for *A–C* and that of 20 msec. for *D*. *E*, tracings of after-hyperpolarizations following double antidromic spike potentials are superimposed after different intervals of ventral root stimulation. *F*, graphical illustration of the after-hyperpolarization that was added to the initial response at the various stimulus intervals in *E*. *G* and *J*, showing, with different sweep velocities, a potential change produced in a motoneurone membrane by applying square pulses of 2×10^{-9} amp. The onset of the pulses is indicated by arrows. Same square pulses as in *G* and *J* were applied at the summit of the after-hyperpolarization following single (*H* and *K*) and two successive (*I* and *L*) antidromic spikes. Time-scale of 20 msec. applies to *G*, *H* and *I* and that of 4 msec. to *J*, *K* and *L*. Below *I* and *L* are shown the artefact potentials in recording *G–I* and *J–L* respectively, being obtained in isolation in the extracellular position by passing the same current as in *G–L* through the microelectrode. Note that records *A–D*, *E–F* and *G–L* were obtained from three different motoneurones.

A slight increase in the intensity of the intracellular pulse (Fig. 1*C*, lower trace) caused the *IS* spike to be set up in every trace and in about half the *SD* spike was also elicited and is seen in the upper trace to result in an after-hyperpolarization which was superimposed on that following the antidromic spike in *A*. When a second current pulse generated an *SD* spike so that there were three *SD* spikes in succession (Fig. 1*D*), there was a further addition to the after-hyperpolarization. It was usually impossible to generate *SD* spikes by antidromic invasion of the motoneurone at brief intervals because the excitability of the *SD* membrane was depressed by the hyperpolarization following the first invasion[1]. However, on occasions where the safety factor in the antidromic conduction was high enough, it was possible to observe the same summation phenomenon of the after-hyperpolarization as described here, merely by using the antidromic stimuli.

In Fig. 1*E* after-hyperpolarizations following two successive antidromic volleys at various intervals are superimposed, and the amount of hyperpolarization added by the second volley is reproduced in Fig. 1*F*. There is seen to be a progressive decrease as the volley interval is progressively shortened. This depression might occur because the equilibrium potential for the after-hyperpolarization is only 20 mV below the resting potential-level. Fig. 1*G*, *J* shows a potential change in the membrane caused by passing a small hyperpolarizing pulse current. In *H* and *K* this pulse current was superimposed on the summit of the after-hyperpolarization that followed an antidromic *SD* spike. It can be seen that the magnitude of the potential change produced by the pulse current in *K* is about 80 per cent of that in *J*, being measured at the end of the pulse current.

In *I* and *L*, when another antidromic invasion occurred at 3 msec. before that in *H* and *K*, the peak size of the after-hyperpolarization was increased by 49 per cent of that in *H* and *K* and there was a marked reduction in the effect of the test hyperpolarizing pulse, the magnitude of the potential change thereby produced in *I* and *L* being 40 per cent of that in *G* and *J* By applying the test pulse at various phases during the single or summated after-hyperpolarization, it was shown that the depression of the test hyperpolarization or depolarization approximately paralleled the amplitude of the after-hyperpolarization

The prolonged after-hyperpolarizations following impulses in mammalian *C* fibres[7] and frog myelinated nerve[8] show also a temporal summation The ionic process of these after-hyperpolarizations has been related to the active transport of sodium and potassium ions that would hyperpolarize the membrane by depletion of the extracellular potassium[7,8] or by driving an electrogenic sodium current[9] In this respect, the after-hyperpolarization in motoneurones, which is generated by the increased potassium conductance, appears to be a unique phenomenon The special significance of the motoneurone after-hyperpolarization has already been discussed[2,10]

Mechanism of Calcification : Inhibitory Role of Pyrophosphate

The mechanism of calcification has been considerably clarified recently[1] Collagen fibrils were shown to possess *in vitro* the property of nucleating hydroxyapatite precipitation and of triggering mineralization[1–3] 'But why does only part of the collagen present in the organism calcify ? Recently, we suggested that the activating sites of collagen and crystal growth could be blocked in the organism by a plasma inhibitor[4] Indeed we showed plasma to contain one or several substances highly inhibitory to apatite precipitation The technique used was to determine *in vitro*, at physiological conditions, the minimum ion product (Ca) × (P) necessary for hydroxyapatite precipitation After addition of plasma, the rise of this minimum product revealed the presence of inhibitors As the inhibitor was shown to be destroyed by alkaline phosphatase, and the polyphosphates to have a strong inhibitory activity at concentrations as low as 10^{-7} M, we suggested this inhibitor to be a polyphosphate However, to our knowledge, no such compound has so far been demonstrated in plasma or in urine

As the concentration of plasma of this hypothetical polyphosphate was bound to be very low (10^{-5} M), we first searched for it in urine, where it was implied to exist, according to our test, in a much higher concentration After isolation, its nature was determined as inorganic pyrophosphate[5,6] The mean 'daily excretion of pyrophosphate in healthy males was found to be 2 16 mg expressed as phosphorus (ε = ±0 20), in adult young women it is below 1 mg, but it increases with age By its highly inhibitory action, the urine pyrophosphate accounts for the supersaturation of urine in calcium and phosphorus Our finding that its mean daily excretion falls to 1 06 mg (ε = ±0 17) in urolithiasic men, suggests that its action is present both *in vivo* and *in vitro*

The presence of pyrophosphate in urine suggests that the plasmatic inhibitor is of a similar composition. Indeed, in experiments recently completed, we could isolate from plasma a phosphorus compound highly inhibitory of hydroxyapatite precipitation which, after purification, migrates on paper chromatography in the same way as inorganic pyrophosphate, with three different solvents (Solvent I isopropanol, 70 , water, 30 , 20 per cent ammonium hydroxide, 0 3 , trichloroacetic acid, 4 g Solvent II methanol, 70 ; 2 N ammonium hydroxide, 30 Solvent III *n*-propanol, 30 , ethanol, 30 , water, 39 , 25 per cent ammonium hydroxide, 1) Its concentration, although very low (10^{-5} M), easily inhibits apatite precipitation Its action at this level cannot be explained by a lower ionic calcium concentration due to the formation of a complex, but it is probably a 'poisoning' of crystal growth

The following mechanism of calcification is therefore suggested Hydroxyapatite precipitation can occur at a physiological concentration of calcium and phosphorus. due to the nucleating function of collagen This property, together with crystal growth, is inhibited by plasma pyrophosphate, which protects the collagen that is not to be mineralized For collagen to calcify, pyrophosphate must be destroyed *in loco* by the enzyme pyrophosphatase, which was shown to be present in mineralizing tissues[7–9]

HÆMATOLOGY

Accelerated Lysis of Blood Clots

In a recent article[1], we described a class of compounds which specifically inhibited cross-linking of the sub-units of the clot network The possibility arose that clot lysis by the proteolytic enzyme system of blood (plasmin) might be greatly enhanced if clotting were allowed to take place in the presence of the foregoing inhibitors, of which glycineamide is a simple example (Of eight glycyl dipeptides so far examined, only those of L-isoleucine, L-valine and glycine showed appreciable effect, emphasizing the specific nature of the inhibition of cross-linking of the clot (unpublished data by L Lorand and K Konishi)) In order to test the effect of this substance on clot lysis, the following experiment was performed 0 8 ml aliquots of freshly drawn (cubital vein) human blood was mixed in glass tubes (*a*) with 0 1 ml of 0 2 M neutral glycineamide and 0 1 ml of purified urokinase (a gift from Abbott Laboratories, North Chicago, Illinois) containing 90 units of the plasminogen activator in 0 15 M neutral sodium chloride, (*b*) with 0 1 ml each of 0 2 M glycineamide and 0 15 M sodium chloride, (*c*) with 0 1 ml each of neutral 0 2 and 0 15 M sodium chloride solutions, and finally (*d*) with 0 1 ml of 0 2 M sodium chloride and 0 1 ml of the urokinase solution containing 90 units of activity

In all samples (each carried out in triplicate), clotting occurred between 6 and 7 min after blood was drawn They were then incubated at 37° Lysis was judged by visual disappearance of the clots, which were inspected at 15-min intervals during the first hour and hourly thereafter for 6 h of incubation Further observations were made at 18 and 24 h

Remarkably, all samples of set (*a*), containing both urokinase and glycineamide, showed complete lysis after only 1 h incubation In contrast, set (*d*), which contained urokinase but no glycineamide, retained undigested clot residues up to 18 h Two tubes of set (*b*), comprising glycineamide but no urokinase, lysed by 24 h, a third tube of this set contained a small clot residue at this time All samples belonging to set (*c*) showed firm, retracted clots at 24 h incubation

Comparable results were obtained with rabbit and rat bloods These preliminary experiments clearly suggest that glycineamide is an adjuvant of clot lysis Pharmacological potentialities of the cross-linking inhibitors[1], in general, are being further explored for possible use in thrombolytic therapy

A Simple Comparative Method of measuring Red Cell Viability

A VARIETY of methods, including use of immunological or isotopic markers or the excretion-rate of products of hæmoglobin catabolism, have been used to estimate *in vivo* viability of red blood cells[1] In measuring the viability of cells subjected to storage or other *in vitro* treatment, it is necessary to calculate survival using an independent measurement of dilution since the experimental cells may in part be rapidly lost[2,3] The dilution volume, or red cell mass, of the recipient has been estimated indirectly from plasma volume and hæmatocrit determinations[3] or directly by use of simultaneous or sequential injections of control red cells marked with a labelling system different from that used for the experimental cells[3,4]

In principle it appeared to us possible to estimate survival of experimentally treated red cells most easily and reliably by direct comparison of test cell survival to that of control cells by use of consecutive injections of the two cell populations each labelled with the same isotope Effects due to differences in isotope elution, biological disposition, or methods of analysis would thus be avoided Chromium-51 has been utilized as the isotope inasmuch as several investigators[5] have demonstrated that red cell volume could be determined repeatedly and reliably in the same recipient using sequential injections of red cells labelled with chromium-51

New Zealand rabbits weighing about 3 kg were used in groups of 4–6 to evaluate the proposed method Autologous control cells, obtained by heart puncture, and homologous test cells were labelled as whole blood with chromium-51 ('sodium rachromate,' Abbott Laboratories), using respectively 10 μc and 100 μc per 15 ml of blood-ACD anticoagulant (3 1) Labelling was allowed to proceed for 30 min at room temperature and was stopped by addition of ascorbic acid (0 4 ml 10 per cent solution) Uptake of chromium-51 was 90–95 per cent of theory Labelled red cells were injected as whole blood without washing

An injection of 5 0 ml of autologous blood labelled with chromium-51 was made into each test animal, followed by duplicate sampling of the peripheral blood between 30 and 60 min for specific red cell radioactivity A second injection of 5 0 ml of homologous test blood, untreated or subjected to storage at 4° C or in the frozen state and labelled with chromium-51 at a 10-fold higher level, was made into the same animal, followed again by duplicate sampling of the peripheral blood for specific red cell radioactivity between 30 and 60 min and at later intervals of time (for example, 24 h)

Total amounts of chromium-51 infused as labelled red cells in each injection were determined on 1 0-ml aliquots of dilutions of the total red cell content of a volume of labelled blood equal to that injected Circulating specific red cell activities were determined for each peripheral blood sample on 1 0 ml volumes of packed red cells measured in syringes graduated to 0 01 ml All blood samples were centrifuged under constant conditions of time and speed Radioassays were carried out with a Nuclear Chicago Corporation model *DS* 5-5 scintillation well counter and model 186 decade scaler

The percentage survival of test red cells was calculated by use of the formula

$$\% \text{ Survival} = \frac{\bar{T}_r - \bar{S}_r}{T} \left(\frac{S}{\bar{S}_r} - V_x \right) 100$$

T and S refer, respectively, to the total net counts per minute infused as labelled red cells in the test and control injections $\bar{T}_r$ and $\bar{S}_r$ refer, respectively, to the average net counts per minute observed in 1 0 ml volumes of red cells following the test and control injections V_x is the difference in volumes (in ml) of test cells injected and of those removed in sampling after the control injection Survivals at 30–60 min and at 24 h are calculated in an equivalent manner using $\bar{T}_r$ determined at the respective time-intervals The higher level of chromium-51 in the test injection reduces to about 0 5–1 per cent the error which would be introduced into the calculation of 24-h viability by a 5–10 per cent loss of control cells in this period of time

Precision of pipetting and counting packed red cells has been ± 3 per cent or better , precision of measuring the injected dose of chromium-51 cells has been ± 1 per cent Mixing of the infused red cells into the circulation occurs rapidly Following injection of normal cells, the specific red cell radioactivity is stable within ± 2 per cent over a period of 6–69 min or more

Table 1 summarizes results obtained in assaying the early and 24-h post-infusion survival of normal untreated rabbit red cells and rabbit red cells subjected to 21-day storage at 4° C or to freezing and thawing in glycerol medium

Table 1 *In vivo* VIABILITY OF CONTROL AND PRESERVED RABBIT RED CELLS

Treatment	No of groups	No animals per group	% Red cell survival (average ± *S D*) 30–60 min	24 h
Control*	11	4–6	99±5	94±5
4° C storage 21 days (with ACD)	2	4–5	77±5	69±1
Frozen in glycerol†	2	6	86±8	80±1

* Untreated, freshly collected homologous cells in ACD (acid-citrate-dextrose)

† Frozen, thawed, and processed according to Jones *et al* (ref 6)

Variation within groups was about ± 10 per cent This has appeared to be largely accounted for in terms of analytical errors Biological sources of variation did not seem important Control cells, of course, must be subjected to a minimum of trauma in order to avoid erroneously high comparative survival figures of the test cells

The advantages of the proposed method lie in the simplicity of sample preparation and radioassay, in the use of chemically and radioactively identical markers for control and test cells, and in the minimum amount of handling required keeping the control cells as nearly normal as is experimentally attainable While our experience has been with rabbit red cells generally, the proposed method is readily adaptable to use with human beings In work to be reported elsewhere, we have in human recipients obtained precision of ± 5 per cent or better when using a ratio between control and test-levels of injected isotope of 2–3 An overall dose of chromium-51 of less than 100 μc or about 1/8 the recommended body burden was used Other cellular components of blood can be labelled with chromium-51, and a similar comparative isotope dilution technique should be applicable to the estimation of their relative viability

RADIOBIOLOGY

Binding of Strontium in Blood

DURING an investigation of the relative availability to man of strontium in bread and cow's milk[1], three normal subjects ingested approximately 500 mμc of strontium-85 daily for 4 weeks Bulked samples of plasma from blood taken thrice weekly showed a lower specific activity (^{85}Sr/Sr) than urine for the same period These results are shown in Table 1 as mean values for the first three subjects Two further normal subjects followed a similar regimen, but less-frequent and larger samples of blood were taken This allowed the specific activity to be determined on each blood sample for comparison with the specific activity of urine over a contemporary 2-h period It will be seen that these results were substantially the same as those in the earlier case , and a similar finding was obtained in another subject given a single oral dose of strontium-87*m*

Table 1

Subject	Date	Specific activity of strontium Urine mμc/μg Sr	 Plasma mμc/μg Sr	Ratio urine/ plasma

"	30/5/62	0 23	0 090	2 6

*Single oral dose

The ratio of the specific activity of strontium urine/plasma was always appreciably greater than unity This implies either that the kidney is able to differentiate between different isotopic forms of strontium, which is most unlikely, or that strontium exists in two different chemical forms in blood and that the kidney is able to differentiate between these Further experiments to investigate this phenomenon are in progress

X-Irradiation of *Escherichia coli*

Escherichia coli is the bacterium probably most commonly used in radiobiological work It is generally agreed that the growth conditions before, as well as after, irradiation affect the number of cells which survive a given X-ray dose Nevertheless, contradictory results have been reported from experiments in which almost identical techniques have been utilized Thus Stapleton *et al* [1] report that irradiated cells recover to a certain extent from lethal effects of X-rays if, prior to incubation at 37°, they are held in presence of available nutrient at temperatures sub-normal for optimal growth, say, 24 hr at

19° Non-irradiated control cells showed no variation in viability with temperature

Opposite results were obtained by Alper[2] In her experiments, holding irradiated cells on nutrient agar for 6 hr at 19° led to an increase in sensitivity, that is, fewer cells survived than in cultures which had either been incubated at 37° immediately after irradiation, or had been kept for 2 hr at 45° and thereafter at 37° Moreover, only 60 per cent of non-irradiated control cells were stated to survive 6 hr at 19° These results are difficult to reconcile with previous reports[3] in which the general principle was evolved that irradiation damage in bacteria is the greater the faster the post-irradiation growth-rate This relation between irradiation effect and growth-rate, however, has not been found to hold good generally[4] and further instances have been described[5] in which bacteria do not conform to this 'principle'.

In view of these contradictory reports it was decided further to examine the part which changes in temperature and growth-rate play in influencing post-irradiation viability in *E coli*

Cells derived from a synthetic medium-agar slant were grown in liquid synthetic medium[6] to reach stationary-state concentration They were irradiated in the same medium in equilibrium with air or with oxygen-free nitrogen

Irradiation was carried out with 200 kVp X-rays, 10 m amp , no added filtration The dose-rate was 8 kr /min Two doses only were given, 4 and 8 kr Suitably diluted samples (0 1 ml) were spread on (Oxoid) nutrient agar and incubated at 37° or 15°, colony counts being made after 1 or 5–6 days, respectively

As in the experiments of Stapleton *et al* [1], temperature did not significantly affect the number of non-irradiated controls There was, furthermore, only a very small difference between the total viable counts of irradiated cells which had been incubated at 37° or 15°, respectively The oxygen enhancement ratio was also very similar at the two temperatures (Fig 1) In appearance, however, the colonies differed greatly, 90 per cent of the controls grown at 15° being petite colonies, the remainder being of normal size, as were all colonies grown at 37° Microscopic examination revealed the petite colonies to be composed entirely of filamentous forms while the large colonies consisted of single cells The ratio petite/large colonies in the surviving fraction of the irradiated cells was different from that in the controls On plotting the survivors of the two types of cells against X-ray dose the filamentous forms were revealed to be more radiation sensitive than single cells and to have a smaller oxygen enhancement ratio (Fig 2) Thus, in order to bring about the same reduction of the viable count in both single and filamentous cells the latter require only about half the dose on irradiation in air and a third of the dose on irradiation in nitrogen

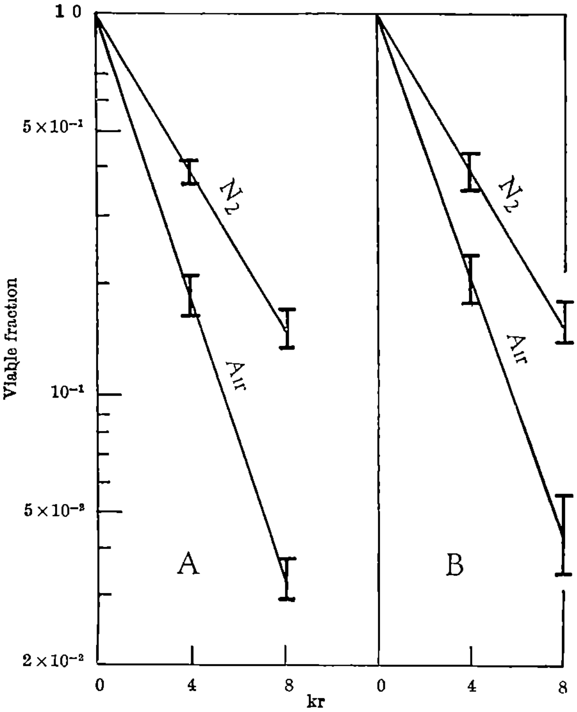

Fig 1 Survival of *E coli B*, post-irradiation incubation at different temperatures, *A*, 37°, *B*, 15° The oxygen enhancement ratio in both cases is approximately 1 6

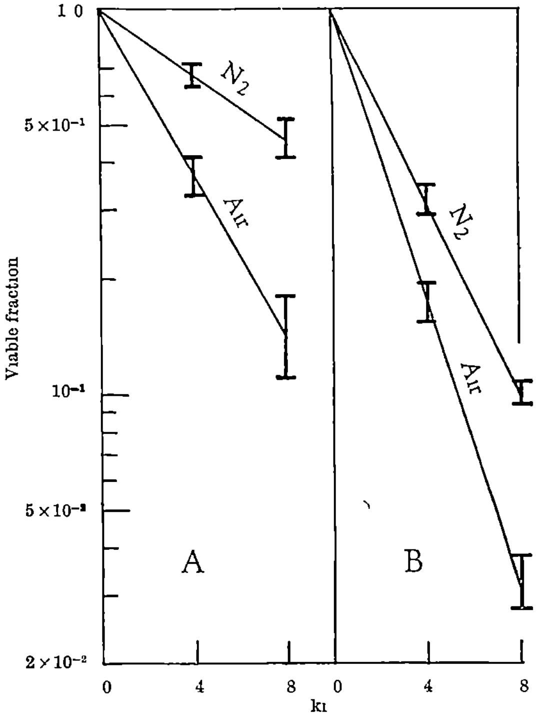

Fig 2 Survival of *E coli B*, post-irradiation incubation at 15° *A* Large colonies, single cells, *B*, petite colonies, filamentous forms Oxygen enhancement ratio in *A* = 2 5, in *B* = 1 5

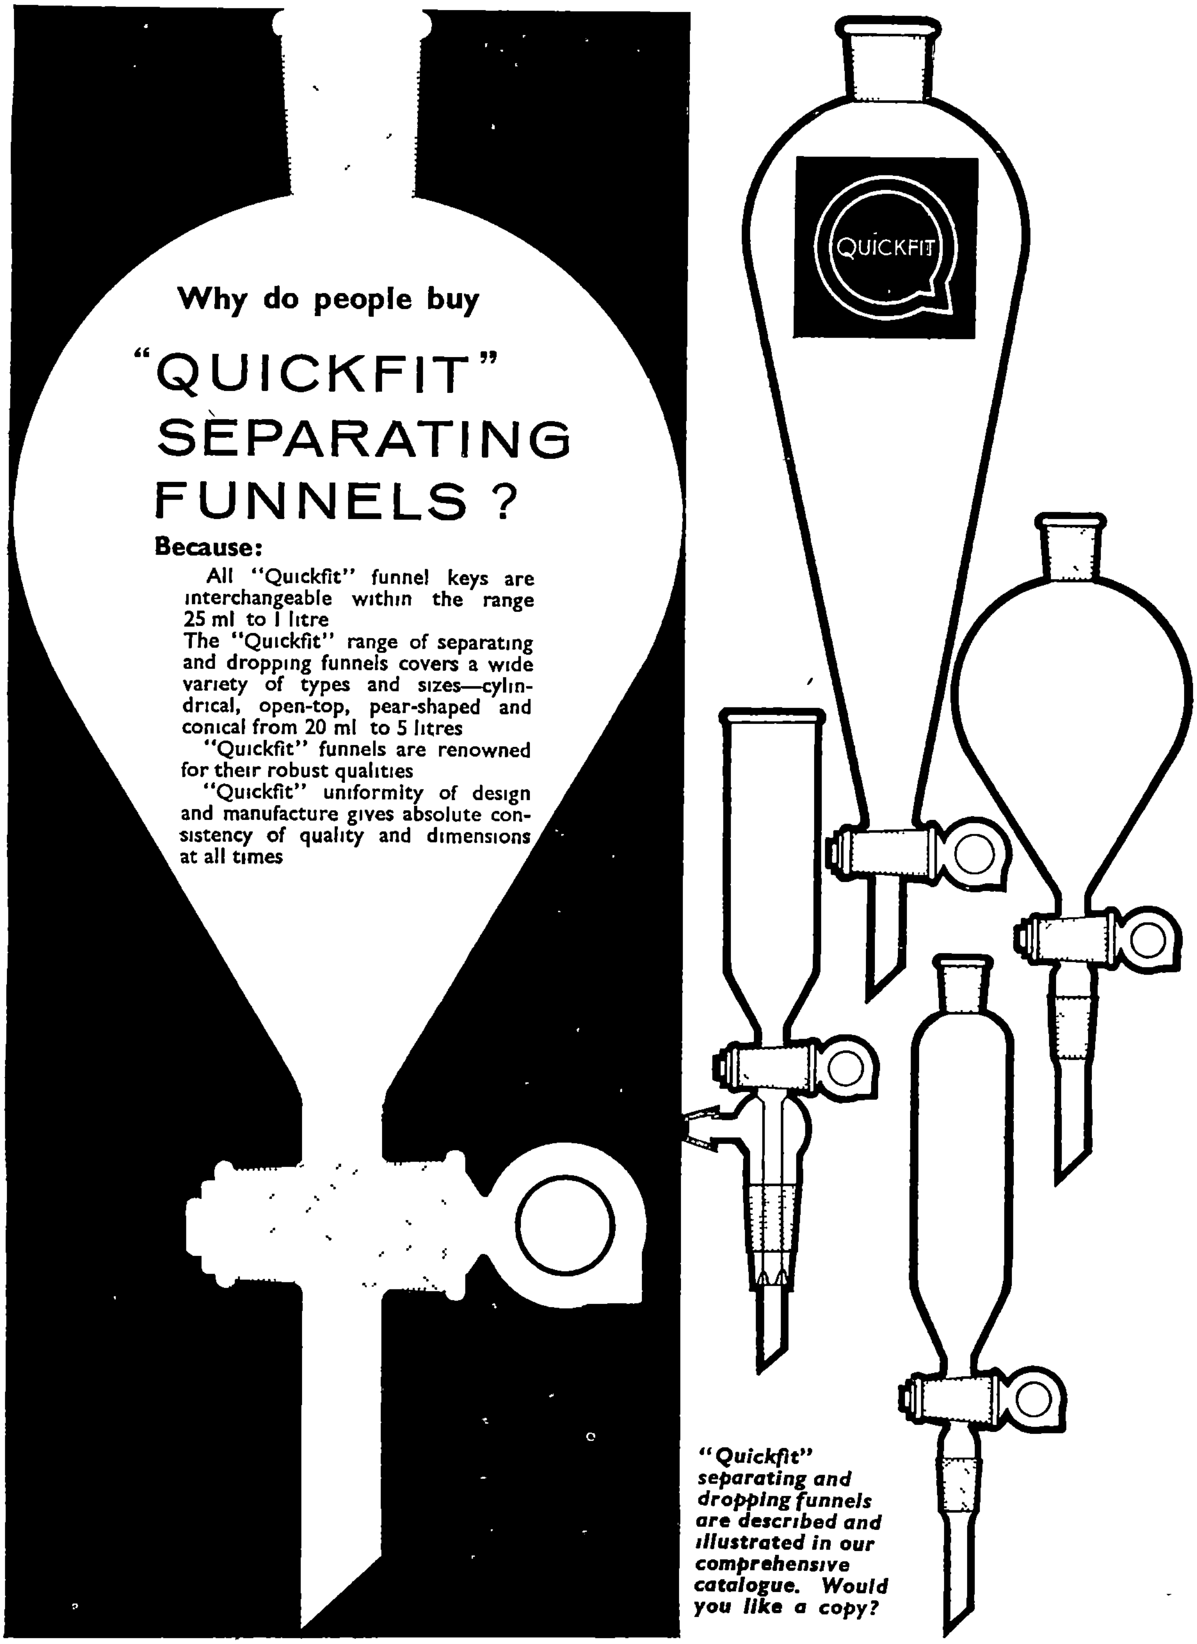
It follows that the culture of *E coli* used was not uniform but contained two types of cells indistinguishable under conditions of optimal growth, except possibly in their metabolism[7,8], but potentially different in their reaction to unfavourable conditions, as low temperature and irradiation.

Cultures were, therefore, grown from single colonies of both types in order to see whether the characteristics of the cells were maintained on growth at different temperatures

The procedure was briefly as follows growth on solid synthetic medium at 24°, followed by growth in liquid synthetic medium at 30°, when all cells are single forms On plating on nutrient agar and incubation at 15° a clear division between large (single cells) and small (filamentous forms) colonies resulted, about 95 per cent of the colonies reverting to the type from which they derived Fresh cultures, grown



Why do people buy

"QUICKFIT" SEPARATING FUNNELS ?

Because:

All "Quickfit" funnel keys are interchangeable within the range 25 ml to 1 litre

The "Quickfit" range of separating and dropping funnels covers a wide variety of types and sizes—cylindrical, open-top, pear-shaped and conical from 20 ml to 5 litres

"Quickfit" funnels are renowned for their robust qualities

"Quickfit" uniformity of design and manufacture gives absolute consistency of quality and dimensions at all times

"Quickfit" separating and dropping funnels are described and illustrated in our comprehensive catalogue. Would you like a copy?

Chemical Analysis: The Working Tools

Volumes I, II, and III

Edited by C R N STROUTS,
H N WILSON, *and* R T PARRY-JONES

Assisted by J H GILFILLAN

In this new edition some of the original text has been rewritten, and out-of-date material removed Four new chapters have been added, the book has been divided into three volumes These deal with fundamental operations of analysis, methods based on electrical and electro-magnetic phenomena, and the analysis of organic substances

Second edition Illustrated
Three volumes £7 7s net

Diffuse X-ray Reflections from Crystals

W. A WOOSTER

This is the first book to attempt a unified treatment of all the various aspects of diffuse reflections It covers elastic properties of crystals, elastic spectra, static distortions of lattices, and shapes and orientation of molecules in crystals, and is written with a minimum of mathematical analysis, at a level suited to the young research worker 35*s net*

Asymptotic Approximations

HAROLD JEFFREYS

This introduction to the subject deals with the main theorems on asymptotic series, the theory of the method of steepest descents, linear differential equations of the second order Special attention is given to uniformity of approximation over regions in the complex plane Applications are made to several special functions and to the theory of diffraction

again from single colonies through two passages at 30° and 37°, were next irradiated and viable counts obtained after incubation at 15°. A clear separation according to cell type resulted once more and viable counts and oxygen enhancement ratios closely resembled those shown in Fig. 2 for single cells and filamentous forms.

The fact that *E. coli* can form filaments in a certain percentage of cells growing under unfavourable conditions complicates interpretation of irradiation effects. Thus cultures which contain an unknown proportion of potentially filamentous, highly radiation-sensitive forms will show correspondingly varying effects of irradiation, especially when this is followed by incubation at a suboptimal temperature during part of the post-irradiation growth period. The conclusion that certain metabolic reactions occurring in the cold cause either attenuation[1] or accentuation of radiation damage in *E. coli*[2] may need reconsideration in view of the experiments reported here. These show that types of *E. coli* can be isolated which, when grown in the cold, are distinct in their form, that is, single or filamentous, and that these differ in their inherent radiation sensitivity.

Deoxyribonucleic Acid Synthesis in Oocytes of Mouse Embryos

IN order to investigate the synthesis of DNA in mammalian oocytes an attempt was made to label oocytes of mice with a radioactive DNA precursor. If DNA is synthesized during the last premeiotic interphase, as it has been reported for the mouse spermatocyte[1], it should be possible to label oocytes by injecting a radioactive precursor during the last third of pregnancy. Meiotic prophase in the mouse oocyte begins about the 13th day of embryonic life[2–4]. Tritium-labelled thymidine was therefore injected into mouse embryos on different days during the latter part of embryonic life to see : (1) whether oocytes can be labelled in this way ; (2) what percentage of the oocyte population is labelled after injection on different days of embryonic life ; (3) whether labelled oocytes in progressive stages of meiosis can be obtained if autoradiographs are prepared at different intervals after injection of the DNA label.

Street mice 13–18 days pregnant were used in this work. On the day of injection of thymidine the pregnant mouse was anæsthetized, her abdomen opened and the uterine horns exposed. 10 μc of tritium-labelled thymidine (Radiochemical Centre, Amersham, England) was injected into the amniotic sac of each embryo. The abdomen of the mother mouse was then closed and the animal returned to her cage, where she usually recovered within a short time. The embryos were killed at different intervals after injection, fixed in Bouin's solution and serially sectioned at 5μ. Autoradiographs of Feulgen-stained sections were prepared with K_2 liquid emulsion (Ilford) and exposed between 7 and 28 days.

Examination of the autoradiographs shows that the nuclei of oocytes can be labelled by this method (Fig. 1). However, the number of cells which incorporate the label varies greatly and depends on the age of the embryo at the time of tritiated thymidine injection. The distribution of labelled oocytes in animals killed 24 h after injection of tritiated thymidine is shown in Fig. 2. The largest number is found when the precursor is injected on the 13th, 14th or 15th day of pregnancy : 27, 35 and 28 per cent of the cells take up the label on these days. Only a small fraction of the oocytes can be labelled if tritiated thymidine is injected after the 15th day of pregnancy. Injection on the 16th day results in 2 per cent of labelled oocytes whereas on the 17th and 18th day only 0·5 per cent of them incorporate the label. The fact that on each of the three days between the 13th and 15th day about one-third of the oocytes incorporate the label, as well as the sudden drop in the number between the 15th and 16th day, suggests that synthesis of DNA in the oocyte is a fairly synchronized process which in most cells is completed by the 16th day of embryonic life. The small number of oocytes incorporating the label after the 15th day could indicate either that synthesis of DNA in these cells extends over a much longer period of time than in the other cells, for this there is no other evidence, or it may suggest that DNA synthesis in these few cells started later in embryonic life. This assumption is

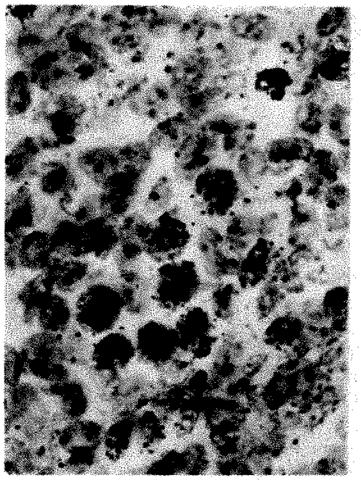

Fig. 1. Labelled oocytes in leptotene. Autoradiograph prepared 24 h after injecting tritiated thymidine into the amniotic sac of a 15-day-old mouse embryo (× 700)

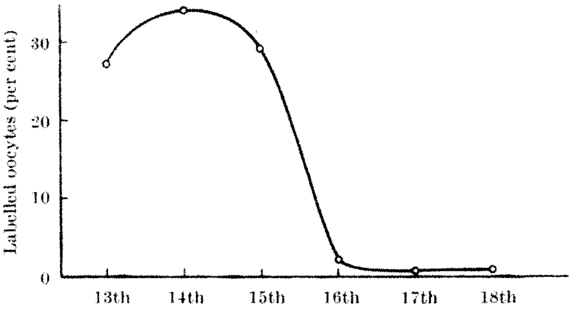

Fig. 2. Distribution of labelled oocytes 24 h after tritiated thymidine injection on different days of embryonic life

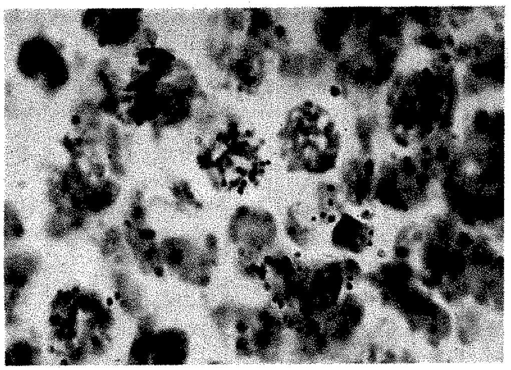

Fig. 3. Oocytes in pachytene, the one in the centre is labelled. Autoradiograph prepared 4 days after injection of tritiated thymidine on the 14th day of pregnancy (× 1000).

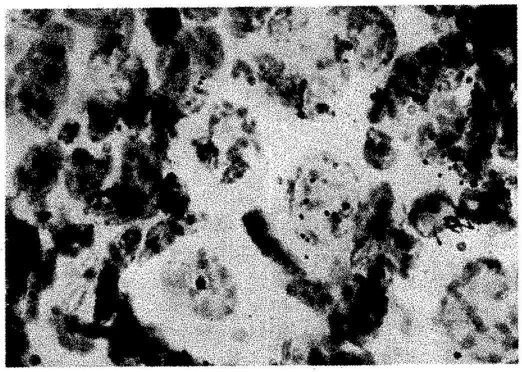

Fig. 4. A labelled oocyte in early diplotene next to an unlabelled one. Tritiated thymidine injected on the 13th day of embryonic life, autoradiograph prepared 8 days later, that is, 2 days after birth of the mouse (× 1000)

supported by the fact that some oocytes in leptotene can usually be found in histological sections of ovaries after the 15th day, indicating that they entered meiotic prophase recently.

The mouse oocyte in the embryo progressively develops and passes through the stages of leptotene, zygotene and pachytene. Just after birth the ovary contains oocytes in pachytene and early diplotene in about equal numbers[5]. Having determined the time of DNA synthesis to be between the 13th and 15th day of embryonic life, one should then be able to find oocytes in the progressive stages if autoradiographs are prepared on animals injected with the labelled precursor on one of these three days and killed later in embryonic life or after birth. This in fact has been done. All progressive stages of labelled oocytes have been observed. If autoradiographs are prepared within 24 h after the injection, the oocytes are in leptotene or early zygotene. If 4 days intervene between the injection and death of the animal, the oocytes have developed to the stage of pachytene, and many in this stage are labelled (Fig. 3). If autoradiographs of ovaries are prepared only after the birth of the animal, many of the labelled oocytes are in early diplotene (Fig. 4), indicating that synthesis of DNA in these cells occurred at the time of injection (13–15th day), and that they kept the label through the progressive development.

It has thus been possible to show that synthesis of DNA in the mouse oocyte occurs mainly on the 13th, 14th and 15th day of embryonic life and that the label incorporated into the oocyte nucleus during DNA synthesis can be followed through the progressive stages of the meiotic prophase until after birth.

BIOLOGY

Terminology of Some Biologically Active Substances and Validity of the Term 'Pheromones'

In 1957 I proposed the term 'telergones' (from the Greek *tele*—afar and *ergon*—action) for the designation of all biologically active substances secreted by animals into their environment and influencing other organisms[1]. These substances are products of external secretion and differ principally by their importance for the animals from hormones, parahormones and other substances which display their physiological action within the organism producing them. The site of production of telergones are special unicellular or multicellular glands, the ducts of which open singly or in groups on to different parts of the body surface or into various cavities opening to the outside. In many instances there are accessory adjustments for pushing out, sprinkling and exhalation of telergones or for introducing them into the body of other animals.

At present, the chemical nature of only few telergones is known. They can belong to various groups of organic substances. Since in various systematic groups of animals the substances with similar biological action can differ greatly in their chemical properties the classification of telergones is now based not on their chemical properties but on their biological importance to the animals producing them.

Telergones are subdivided into 'homotelergones' acting on other individuals of the same species and 'heterotelergones' acting on animals belonging to other species[1,2].

Karlson and Lüscher[3] have proposed the term 'pheromones' for the designation of those substances which I called 'homotelergones'. They derived this new term from the Greek *pherein*—to transfer and *hormān*—to excite. But Micklem[4] justly pointed out that in the word 'pheromone' there is no structural clue to its derivation from *hormān* and corrected it into 'pherormone'. Then Karlson and Lüscher, in a note to Micklem's article, gave a new etymological explanation for their term. They stated that the ending 'mone' was regarded as a proper suffix used in such scientific terms as hormones, gamones and termones[4].

However, the use of the term 'homotelergones' is to be preferred since it was proposed earlier and is more correct etymologically than the term 'pheromones'. Moreover it indicates exactly the relation of these substances to the telergones and their action on other individuals of the same species.

The substances belonging to the homotelergones are subdivided into the following groups:

(1) 'Gonophyones' (from the Greek *gonos*—sex and *phyein*—to create) acting on the development of the

sex glands and the formation or modification of the sex characteristics (for example, the substances produced by the females of the echiurid worm *Bonellia viridis*, by marine snails of the genus *Crepidula* and the royal jelly of bees).

(2) 'Gamophyones' (from the Greek *gamos*—marriage and *phyein*—to create) stimulate the maturation of the sex glands and the onset of the reproductive processes in the individuals of the other sex (such substances have been established in polychætes *Nereis* and *Grubea* and in some fishes).

(3) 'Epagones' (from the Greek *epagein*—to attract) are attractants of other individuals of the same species, most frequently of the opposite sex (for example, the sexual odoriferous substances of mammals, insects and other animals).

(4) 'Odmichniones' (from the Greek *odme*—odour and *ichnion*—trace) are deposited on the ground and other surrounding objects and serve for marking the locality and facilitating the orientation, such substances are produced by ants, termites and some mammals).

(5) 'Thorybones' (from the Greek *thorybein*—to provoke alarm) excite alarm reactions in other individuals of the same flock or shoal (such substances have been detected in fishes by von Frisch[5] and called *Schreckstoffe*; they are produced also in the mandibular glands of some ants).

The heterotelergones are subdivided into the following groups:

(6) 'Amynones' (from the Greek *amynein*—to drive away)—protective or repulsive substances protecting animals against the attacks of their enemies. Some of them have a repulsive odour, others irritate the skin or mucous membranes, and still others possess strongly poisonous properties.

(7) 'Prohaptones' (from the Greek *pro*—before and *haptein*—to snatch or to bind fast) are poisonous substances paralysing or killing the prey.

(8) 'Lichneumones' (from the Greek *lichneuma*—dainties) are produced by some myrmecophiles and termitophiles, greedily licked off by the ants and termites and show excitant or narcotic actions in them.

(9) 'Xenoblaptones' (from the Greek *xenos*—host and *blaptein*—to injure) are produced by parasites and have specific influences on the structure and physiology of their hosts.

The physiological mechanism of action is recognized only in few telergones. Some of them act on specialized chemical receptors (olfactory, gustatory and other) and provoke characteristic reflex actions by their irritation. Evidently in marine and fresh-water animals some telergones from the surrounding water percolate through the intact integument, the surface of the respiratory organs or the alimentary canal into the internal environment of the organism. Dispersed by blood or other circulating fluids through the whole body, they act on organs and tissues sensitive to them. The influence of the telergones on enzyme systems and the participation of hormones in the mechanism of their action has not been studied very much.

Synthesis of Organic Acids in the Fruit of the Grape

TARTARIC and malic acids are the quantitatively important acids in the fruit of the grape (*Vitis vinifera* L.). These acids are believed to be synthesized in the leaves and translocated to the fruit[1,2]. However, there is little experimental evidence to support this theory. The work reported here was undertaken to determine whether organic acids are also synthesized in the berry.

In one typical experiment, performed on July 28, 1961, carbon dioxide labelled with carbon-14 was presented to the leaf immediately above the cluster on a girdled shoot of a mature Sultanina (syn. Thompson Seedless) vine. The fruit was hard, green, and immature. Eleven hours after the start of the $^{14}CO_2$ treatment, the phloem transport from the vine to the fruit was eliminated by girdling the shoot just above and below the cluster. At the same time, the treated leaf was removed. At intervals thereafter, the alcohol-soluble constituents of samples of the fruit were extracted. The cations were removed from the extract with 'Amberlite *IR*-120 (H^+)'. The organic acids were separated on a 'Dowex 1 × 8' column ($CO_3^{=}$)[3]. Malic and tartaric acids were then separated on a 'Dowex 1 × 8' column (formate)[4]. The radioactivity of the various fractions was measured at infinite thinness under a thin window, gas-flow counter.

The results (Table 1) showed that the amount of radioactivity in the organic acids increased as the time after isolation of the fruit from the carbon-14 source was lengthened. Similar results were obtained when berries were isolated by detaching them from the cluster. 62–73 per cent of the radioactivity found in the organic acid fraction was incorporated into malic acid and about 15 per cent into tartaric acid. The relative specific activity of both acids increased three-fold between the two sampling times shown. Stafford and Loewus[5] exposed detached grape leaves to $^{14}CO_2$ and found that 76–90 per cent of the label in the organic acid fraction was in malic acid and only 0·08 per cent in tartaric acid.

Table 1. RADIOACTIVITY IN THE ORGANIC ACIDS OF GRAPE BERRIES AFTER ISOLATION OF THE FRUIT FROM THE SOURCE OF CARBON-14

	Time (h) after isolation of berries		
	1	13	37
Activity in organic acids			
c.p.m. × 10^{-3}	210	272·7	510·6
% of activity in original extract	11·2	14·5	28
Activity in malic acid			
% of activity in organic acid fraction	62	—	73
specific activity (c.p.m. per μequiv.)	60	—	175
Activity in tartaric acid			
% of activity in organic acid fraction	13	—	15·5
specific activity (c.p.m. per μequiv.)	12	—	40

In another experiment, $^{14}CO_2$ was presented to the cluster on July 30, 1961. Samples of fruit were collected at 1 and 23 h after the start of the treatment with $^{14}CO_2$. The proportion of radioactivity found in the organic acid fraction increased from 30 per cent in the first sample to 43 per cent in the second sample.

The results indicate that the berry is an important site of synthesis of organic acids. It has been shown that acid content of the berry increases until cell division ceases[6]. The high level of incorporation of label into tartaric acid by the immature berry relative to that shown by mature leaves[5], suggests tartaric acid synthesis in the grape may be related to some aspect of growth metabolism. This is not inconsistent with the hypothesis that a sugar is the precursor to tartaric acid[5]. The high level of activity found in the organic acid fraction when $^{14}CO_2$ was presented to the cluster indicates that fixation of carbon dioxide into malic acid may make important contributions to the acid content of the berry.

Floral Initiation of *Xanthium* in Response to Application of an Extract from a Day-Neutral Plant

A PROCEDURE for the preparation of a floral initiating extract from the leaf tissues of *Xanthium strumarium* has been described in an earlier report[1]. In general, the procedure involves the rapid freezing in liquid nitrogen of fresh leaf material obtained from flowering *Xanthium* plants. The frozen tissue is lyophilized at temperatures below 0° C. In recent work the continuous extraction procedure has been modified and extraction of the dry leaf material is now accomplished by several washings with cold (0–10° C.) absolute methanol. The methanol is removed at a low temperature by evaporation at reduced pressure in a Rinco apparatus. The residue is diluted with 1·5–5 times its weight of lanolin and the mixture applied as a coating to the under surface of the leaves of vegetative *Xanthium* test plants. All treated plants and their corresponding controls are maintained until dissection on strict long-day conditions. Three weeks after treatment the plants are dissected and the extent and degree of flowering is recorded according to a standard procedure[2].

In the intervening year since the original work was reported we have repeatedly demonstrated the activity of the extract in causing initiation of flowers in *Xanthium*. Recently we have found the extract capable of causing floral initiation in *Xanthium* under conditions of continuous illumination of approximately 2,000 foot-candles intensity from a fluorescent light source. In a typical experiment 40 per cent of the treated plants flowered with all the untreated control plants remaining vegetative.

Extracts prepared from the indigenous sunflower *Helianthus annuus*, a day-neutral plant, also have been found capable of initiating flowering in *Xanthium* test plants. Leaves from flowering *Helianthus* were picked in the late summer of 1961 and were processed and extracted in accordance with the previously described method for obtaining *Xanthium* extract. In one of several successful experiments, 200 g of lyophilized *Helianthus* leaf material yielded 34 g of extract residue. The residue was blended with 50 g of anhydrous lanolin and applied to the leaves of 40 vegetative *Xanthium* plants. A group of 40 untreated plants was used as controls. All plants were then maintained on long-day conditions of 18 h of light and 6 h darkness at 25° C. for the subsequent three weeks. The plants were then dissected. All the control plants were vegetative. Twenty per cent of the treated plants flowered; of those flowering the average floral stage[2] at the time of dissection was 1·2.

The initiation of floral development in *Xanthium* in response to application of *Helianthus* extract strengthens the belief that there is a common chemical substance or closely related series of chemical substances governing the transition to flowering in many plants. Although the evidence is as yet incomplete, the active entity in the extracts is presumed to be the flowering hormone, florigen.

This investigation was supported by National Science Foundation grants Nos. 10854, 10855 and 14380.

Bud Rot Disease of the Oil Palm

FOR many years, a pathological condition of the oil palm, *Elaeis guineensis*, in which the spear and bud tissue becomes rotten, has been known, and has been reported from many countries where the palm is in cultivation. In general, the disease is occasional, but in some areas the incidence is high, and it has caused the death of a large number of palms in the plantations in South Congo.

Numerous possible agents have been suggested as causal, but in spite of many attempts at diagnosis, no one has succeeded in reproducing the condition.

The disease has now been shown to be due to a bacterium of the genus *Erwinia* and similar to *E. lathyri* (Manns and Taubenhaus) Holland, but only on palms which have become, or have been made, susceptible.

Continuous growth studies made on a group of palms in the geneological block at Branbanta (South Congo), show that before an attack of bud rot takes place, the growth-rate of the palm slows considerably. Natural rotting commences some three weeks after this in the region below the point of visible emergence of the spears through the funnel formed by the older leaf bases. If, however, the palm is inoculated immediately a slowing of growth is apparent, an attack can be started within two or three days. Rotting has also been induced by inoculation on palms which have remained for long periods on, or just above, the apparent threshold of susceptibility without succumbing to natural attack. Palms maintaining a normal growth-rate, that is, vigorous palms, have been inoculated, but invariably without effect.

Healthy palms can be made susceptible, and attacks of bud rot have been produced by both root and leaf cutting. A tourniquet applied low on a young spear renders that spear susceptible, but only above the tourniquet.

Inoculation experiments on detached spears show that the most susceptible tissue is that lying 15–25 cm. below the point of emergence of the spear. This is the area where growth is changing from elongation to maturation. Mature tissue is not susceptible, and the very young tissue near the bud is also comparatively resistant. Thus it appears that the bacterium is only able to attack palms which are unable to carry the spear tissue through this susceptible stage, sufficiently vigorously. Different genetical lines show different susceptibilities, and the lines which exhibit the greatest vegetative vigour are also the lines which are least attacked.

Growing conditions in South Congo are marginal. The soil is a poor sand and there is a prolonged dry season. However, wild palms, in which, presumably, natural selection has been operating, are rarely seen affected, and the occurrence of highly productive palms in devastated areas, together with the differences to be found in the geneological blocks, indicate that, while a bacterium is finally responsible, the root cause of the trouble is genetical, in that the material planted is not adapted to the rigorous growing conditions.

A full paper on this work will be published later.

My thanks are due to the Commonwealth Mycological Institute for the identification of the bacterium, and to Unilever, Ltd., for permission to publish this communication.

Compensatory Growth of Cattle on the Natural Grasslands of Northern Rhodesia

ON the natural grasslands of Northern Rhodesia cattle gain weight during the rainy season, but during the subsequent dry season they frequently lose up to 15 per cent, and in some cases as much as 25 per cent, of their previous maximum weight. It is well known that the greater the restriction in feed supply the greater the gain in weight on subsequent realimentation[1-4]. The degree of compensatory growth was measured for the indigenous (*Bos indicus*) Sanga and Zebu cattle (oxen). The level of nutrition was varied during the dry season to produce a range of changes in weight from slightly above maintenance to large losses, and the gains in the following rainy season were observed when all the cattle were grazed as one herd on the natural veld. A summary of the results is given in Table 1. Each age-group trial began at the end of a rainy season during which all the cattle had been under the same conditions. About one-fifth of the cattle were used in more than one year. The stocking-rate was such that ample forage was available during the rains, and the nutrition of the cattle was restricted only by the seasonal decline in the nutritive quality of the grasslands.

Table 1. AGE-GROUPS AND SUMMARY OF CATTLE WEIGHTS

	Cattle ages (yr.)	Mean initial weight (lb.)	No. of cattle	Weight gain (lb.) Dry season Mean	Weight gain (lb.) Dry season Max.	Weight gain (lb.) Dry season Min.	Weight gain (lb.) Rains Mean
1958/59	2	390	18	20	59	– 34	178
	3	669	38	– 8	86	– 80	213
1959/60	2	371	19	– 1	61	– 53	231
	3	580	17	– 28	58	– 157	226
	4	872	39	– 119	12	– 211	254
1960/61	2	372	16	15	82	– 80	190
	3	671	25	– 69	20	– 144	247
	4	778	16	– 60	24	– 176	197
	5	927	28	– 105	26	– 262	192

The response of the cattle on re-alimentation to the different levels of nutrition during the dry season was estimated by the linear regressions of the gains in weight during the rains on the gains during the preceding dry season. It has been suggested[5] that there may be a fundamental difference in response according as the degree of restriction permits small gains, maintenance or losses in weight. There was no evidence of a change in the pattern of response with these conditions, as shown by curvature in the response relationship, even with the widest range of weight changes extending to severe losses. Similar work in North America[6] and elsewhere showed no significant and consistent departure from linearity over the ranges studied. The residual variation was also of the same order as that observed by others[7,8] with groups of similar size.

The regression coefficients (Table 2) show by how much the gain during the rains was expected to be reduced for each 1 lb. increase in dry season gain (obtained by extra feeding) or alternatively, the expected amount by which the rains gain was increased in compensation for each 1 lb. lost as a result of a lower plane of nutrition during the dry season. This regression coefficient thus provides a measure of compensatory growth. It is more general than the recovery index defined for two planes of nutrition[5].

Table 2. COEFFICIENTS OF REGRESSION OF WEIGHT GAIN DURING RAINY SEASON ON GAINS DURING THE PRECEDING DRY SEASON

	Age of cattle (yr.) 2	3	4	5	Average
1958/59	– 0·427 ± 0·259	– 0·710 ± 0·189			– 0·568
1959/60	– 0·519 ± 0·130	– 0·682 ± 0·107	– 0·799 ± 0·100		– 0·667
1960/61	– 0·271 ± 0·124	– 0·710 ± 0·194	– 0·883 ± 0·125	– 0·642 ± 0·099	– 0·626
Mean regression (eliminating years)	– 0·369 ± 0·088	– 0·697 ± 0·093	– 0·822 ± 0·080	(– 0·642) (± 0·099)	– 0·632

The compensatory growth was less with the 2-year-old oxen than with the older groups (Table 2), possibly because they were at a more critical stage of development[5]. Under the conditions of these trials, the regressions were consistent from year to year for each age group, except the 2-year-olds.

The seasons were separated by using the dates of minimum and maximum cattle weights as end-points. The rainy seasons during the three years of the trial were reasonably typical, and varied only from 188 days to 218 days. A more detailed study of the mean growth-curves of selected sub-groups of cattle indicated that the effect on the regression coefficients due to variation in the duration of the rainy season is unlikely to exceed 7 per cent. The growth-curves suggest that the compensatory growth effect persists throughout the rainy season.

The cattle were all offered identical herbage during the rains, and the quantity of fæces produced was used as a measure of relative herbage intake. The cattle which had large weight losses in the preceding dry season consumed more herbage than those on a higher (maintenance) plane of nutrition. This result agrees with those obtained by others[9].

A quantitative knowledge of the response relationship provides a basis for an economic assessment of alternative systems of management. The average costs of feeding to produce various weight changes during the dry seasons can be compared with the values of the corresponding live weights at the end of the growing life of the cattle.

In vivo Isolation of *Hymenolepis nana* and Antibody-binding Sites

A RECENT preliminary investigation[1] suggests that antibodies are directed against adult specimens of *Hymenolepis nana* while located in the ileum of the mouse. The present investigation was carried out to substantiate tentative conclusions regarding the specificity of antibody binding sites previously observed. It appeared, from the earlier experiments, that antibodies were readily available to adult tapeworms, *in situ*, in that binding sites were partially or completely occupied in the adult stage as ascertained by immunofluorescent staining. Specimens were not, in view of antibody access and possibly excess, available for negative controls. *In vivo* isolation of the parasites from direct cellular contact and source of antibody for a period of time longer than the half-life of the mouse immune globulin was therefore considered. Under these conditions, previously localized sites should not exhibit fluorescence following application of indirect immunofluorescent staining.

Under similar conditions the direct technique could be used, utilizing an anti-*Hymenolepis* rabbit globulin, for a comparison of binding sites from the point of view of availability of antigens to the host during infection.

In present experiments, adult worms, obtained from mice following a three-week egg-induced infection, were transferred through several rinses of sterile phosphate-buffered saline of *p*H 7·2 and then incubated at 37° C. for 15 min. in 'CulturStat Medium 199' containing Earle's base, penicillin and streptomycin (Cappel Laboratories, West Chester, Penn.). This medium was selected since in previous experiments adult tapeworms were maintained *in vitro* at 37° C. for more than 30 days (unpublished results). Single worms were placed in individual sterile (autoclaved) diffusion chambers which had been previously moistened with the culture medium. The chambers were of the 'Sellotape' design[2] utilizing type *GS* porosity 'Millipore' filters having a diameter of 8 mm. The filters were immediately implanted, intraperitoneally, in mice which had never been infected with hymenolepids, as determined by fæcal and serological examinations. The surgical procedure was carried out under 'Nembutal' anæsthesia and aseptic conditions. Two chambers were placed in a 23 gm. mouse and removed 3–7 days following implantation. Worms were then subjected to direct and indirect immunofluorescent staining. Conjugates for direct staining were prepared with 'Lissamine Rhodamine *B* 200' (ref. 3) and fluorescein iso-thiocyanate conjugates for indirect staining were obtained from Nutritional Biochemicals Corp., Cleveland, Ohio. Control adsorptions were used as cited in ref. 1. Fluorescent microscopic observation of whole mounts, and frozen sections, was accomplished by utilizing a Reichert-Hacker assembly and microscope with appropriate filters.

Although worms survived in chambers implanted for seven days (a longer period was not attempted), partial encapsulation of several chambers with fatty host tissue was observed which undoubtedly affected diffusion-rates of oxygen, carbon dioxide, liquid nutrients, and metabolic products. Worms from encapsulated chambers, although viable, nevertheless appeared abnormal morphologically.

Fluorescence of previously localized binding sites, in worms obtained from the ileum, was not observed following indirect staining of isolated worms with rabbit anti-mouse globulin. Tapeworms obtained from chambers implanted for only three days did not fluoresce specifically, which is not inconsistent with the catabolic decay period for mouse globulin. Fluorescent sites in isolated worms treated with mouse antiserum and then subjected to indirect staining were not distinguishable from sites observed in worms obtained from the ileum (Fig. 1). This was considered of interest since antibodies which materialize in the intestinal lumen may be somewhat distinct from those appearing in the blood stream, as observed by Barksdale and Ghoda[4] in patients with dysentery caused by *Sh. flexneri* or *Sh. sonnei*.

Antibody binding sites fluoresced strongly in worms obtained from diffusion chambers following direct immunofluorescent staining (Fig. 2). A comparison of these sites with those observed in tapeworms from the ileum did not permit conclusions concerning the number of antigens available during some stage of the infection. Immunoelectrophoretic investigations[5], however, indicate that whereas crude worm extracts possess at least nine antigens (or determinant groups) which engender antibodies in the rabbit, only four elicit a response in the mouse host during infection.

Results indicate that antibodies combine with adult worm antigens *in vivo*. It is not presumed that such antigens are, necessarily, stage specific.

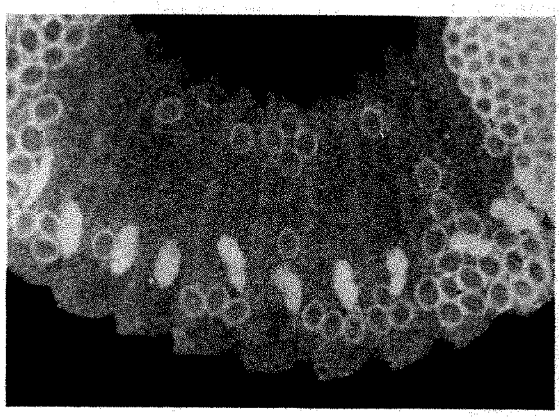

Fig. 1

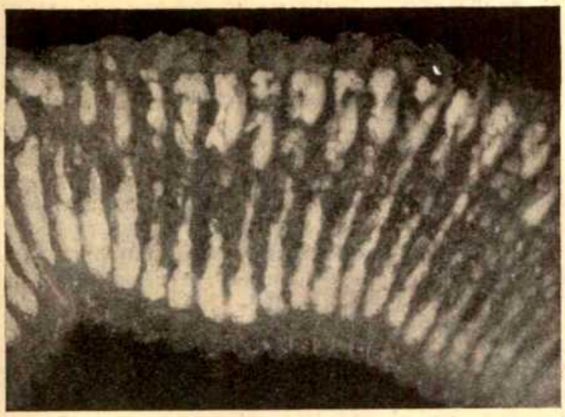

Fig. 2

Utilization of the diffusion chamber technique is suggested as a possible approach to immunological studies requiring *in vivo* isolation of animal parasites.

This investigation was supported by a research grant, *G* 14342, from the National Science Foundation.

Transatlantic Journey of a Tagged Cod

ALTHOUGH cod (*Gadus morhua*) populations in the North Atlantic form more or less discrete stocks, many tagged cod have travelled long distances, for example, between Iceland and Greenland, from Iceland to the Faeroes, and the Faeroes to the North Sea[1], and from Bear Island to Iceland and Greenland[2]. Since 1956 more than 4,000 cod have been tagged in the central North Sea from English vessels, and until this year none had been returned from outside the North Sea. On January 4, 1962, the Lea-type tag[3] No. 1137 which had been attached by a monofilament nylon loop between the first and second dorsal fins to a cod caught on the North-west Rough (central North Sea, 55° 6′ N., 1° 24′ E.) on June 9, 1957, was handed to Mr. G. R. Williamson by a member of the crew of the Polish stern trawl factory ship *Kastor* at St. Johns, Newfoundland, as having been caught on the Grand Banks. At the time no special significance was attached to this fish, as it was presumed to have been tagged in the Newfoundland area. When the exceptional movement was known, further inquiries were made through Mgr. Jozef Wolek, director of the Polish Sea Fisheries Institute, Gdynia, who visited the ship and interviewed the fishermen. They confirmed that the fish was caught on December 7, 1961, on the north-eastern slope of the Grand Banks (47° 54′ N., 47° 54′ W.) in 300–320 m., as witnessed by several fishermen, including the second mate. The fish was still alive, with the tag attached normally, and was measured before the tag was removed and the fish sent for filleting and freezing. It had grown from 57 cm. total length when tagged to 75 cm. when recaptured. In the North Sea a 60-cm. cod might grow 15 cm. a year, but on the north-east slopes of the Grand Banks only about 3 cm. a year.

It is impossible to make more than a guess at the route by which the fish moved. The shortest route around the north of Scotland is a distance of more than 2,000 miles, which would be one of the longest distances travelled by a tagged cod, if not the longest, though it would be by no means impossible in the four and a half years since tagging. It is more probable that the fish travelled via the Faeroes, Iceland and Greenland, or even farther north.

Cultivation of *Eisenia foetida* (Sav.) Free from Infection with Acephaline Gregarines

A PLENTIFUL supply of earthworms known to be free from any infection by acephaline gregarines is required for the examination of the mode of transmission of these parasites. Vigorous cultures of *Eisenia foetida* (Sav.) free from any gregarine infection were successfully established by means of the following technique.

Cocoons gathered from laboratory cultures of the wild host worm were washed thoroughly for 15 min in a flour sieve with a strong jet of water, and then surface sterilized in Nance's solution (0·1 per cent mercuric chloride in 0·5 per cent 'Teepol') for 1 min. They were then washed again for 5 min and finally placed in non-infective soil. The latter was contained in metal biscuit tins holding some 10 lb. of moist soil and having a layer of activated animal charcoal at the base. Each container received 50 cocoons before being set aside, with the lid replaced, to allow the worms to develop. The main difficulty experienced was the preparation of soil which was non-infective, but which would yet support the normal growth of worms from the cocoons. This was finally achieved by first sterilizing the soil in the biscuit tins and then recolonizing it with as many of its living constituents as possible without re-admitting gregarine sporocysts.

The soil was autoclaved, already in the biscuit tins, for 3 h at 60 lb./in.^{2}. Sterility was judged to be complete when attempts to culture fungi on 'Dox' agar and bacteria on nutrient agar from soil inocula failed. (It appeared that the type of soil used was of some importance, the most successful being a light friable loam, the least, a mixture containing dung.) The sterilized soil was now inoculated with a crumb of normal soil in order to re-introduce living constituents. In order to prevent the re-entry of gregarine sporocysts this inoculum was packed into the middle of a glass cartridge (open at both ends) between two firm plugs of sterilized soil (Fig. 1). Soil organisms capable of growth or movement would gradually recolonize the sterilized soil, while any gregarine sporocysts, being non-motile, would remain inside the cartridge. The latter was removed intact 4–6 weeks after implanting, at which time profuse growth of common soil fungi and bacteria could be obtained by plating suspensions of the remaining soil on appropriate media. Even so, such soil would not support

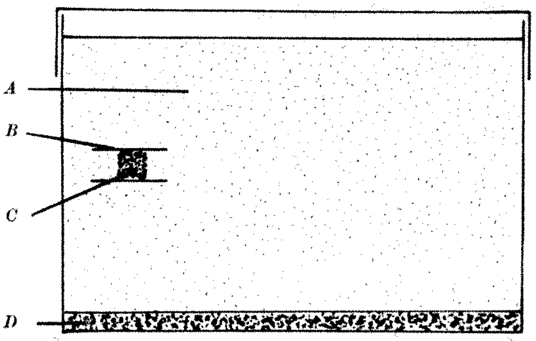

Fig. 1. Method of inoculating sterilized soil with normal soil so as to exclude gregarine sporocysts. *A*, sterilized soil; *B*, glass cartridge containing inoculum of normal soil (*C*) sandwiched between two plugs of sterilized soil, *D*, activated animal charcoal

the growth of worms to full size and sexual maturity until it had been further inoculated with soil protozoa. The method of doing this which was first adopted was to culture soil protozoa in soil extract or hay infusion[1]. A crumb of normal soil was placed at one side of a Petri dish of culture medium which was then incubated for seven days at 24° C. Then an aliquot of the medium was withdrawn from the side of the dish opposite to the point at which the crumb had been added and used to inoculate fresh culture medium.

The subculture after further incubation for 7 days, containing protozoa (mainly ciliates and flagellates) could safely be used to inoculate soil, as any gregarine sporocysts, being non-motile, would have been left behind in the first Petri dish. Later, a less-laborious method of obtaining soil protozoa free from gregarine sporocysts was used in which humus-rich soil was shaken in distilled water, then after standing for 1 h to settle the water was decanted off and filtered through butter muslin. This supernatant was spun at relative centrifugal force 400 for 5 min and then incubated at 24° C overnight. Centrifuging would take down any gregarine sporocysts (which are denser than water) while, as subsequent examination showed, motile micro-organisms recolonize the upper layers of fluid during the incubation overnight. The upper two-thirds of each vessel of soil water so treated was carefully pipetted off and used to inoculate soil which had previously been inoculated with a crumb of normal soil some four weeks earlier, in the manner already described.

The soil now proved an entirely successful culture medium for *E. foetida*. Successive generations have been grown in it continuously over a period of more than 3 years, the only regular further addition being food material in the form of oatmeal. At laboratory temperatures around a mean of 15° C worms develop from cocoon to maturity in 6–7 months. This compares with 3 months growth period reported by Herlant-Meewis[2] for this species when grown in untreated soil at 19° C. No worms cultured under the conditions described here have ever shown infection with acephaline gregarines apart from those infected experimentally.

MICROBIOLOGY

Trypsin Inhibitors produced by *Clostridium botulinum* Cultures

TRYPSIN inhibitors have been demonstrated in a large variety of biological material, involving, among others, pancreas, milk, egg-white, blood, placenta, urine, skin, gut parasites, beans, peas, potatoes[1] and bacteria[2]. In this communication the presence of trypsin-inhibiting material in the culture supernatants of *Clostridium botulinum*, types *A*, *B* and *E*, is reported.

The organisms utilized were *Cl. botulinum* type *A* strain Hall (obtained from Dr. C. Lamanna, Johns Hopkins University, Baltimore), *Cl. botulinum* type *B* strain Beans (obtained from Dr. J. Keppie, Ministry of Supply Experimental Station, Porton), and *Cl. botulinum* type *E* strain Fredriksberg (obtained from Dr. H. O. Pedersen, Copenhagen).

For the cultivation of the types *A* and *B* the media used by Bonventre and Kempe[3] were utilized. For type *E* the medium of Gordon *et al.*[4] was used. The incubation temperatures of the types *A* and *B* cultures were 35° C and for type *E* 28° C.

Samples were withdrawn from the cultures with 24-h intervals for 6 consecutive days. An aliquot was used for turbidimetrical determinations of bacterial growth at 600 mμ. The rest of the sample was centrifuged at 5,000 rev/min for 20 min in order to remove the bacteria, and the supernatant was used for the demonstration of trypsin-inhibiting activity.

A modification of the procedure described by Kunitz[5] was used for the demonstration of trypsin-inhibiting activity. A 3 per cent casein solution was adjusted to *p*H 7·6 with dilute sodium hydroxide. 5 ml. of the casein solution were placed in each of four test tubes (1·7 × 18 cm), 2 ml. of 0·1 M phosphate buffer (*p*H 7·6) were added to tubes 1 and 2, while 2 ml. of the culture supernatant were added to tubes 3 and 4. To tubes 1 and 3 1 ml. of 0·025 per cent solution of trypsin (Difco, 1 : 250) in phosphate buffer was added, while 1 ml. of boiled trypsin solution was added to tubes 2 and 4.

The mixtures were incubated at 37° C in a water bath. After 3 h, 3 ml. of each incubation mixture were added to a tube containing 3 ml. of 10 per cent trichloroacetic acid, mixed, and left at room temperature for 30 min. The precipitated material was then centrifuged at 5,000 rev/min for 15 min. The supernatants were diluted ten-fold with 5 per cent trichloroacetic acid and measured at 280 mμ in a Beckman spectrophotometer, model *DU*, using 5 per cent trichloroacetic acid as blank.

Fig. 1 shows the occurrence of trypsin inhibitors in typical experiments.

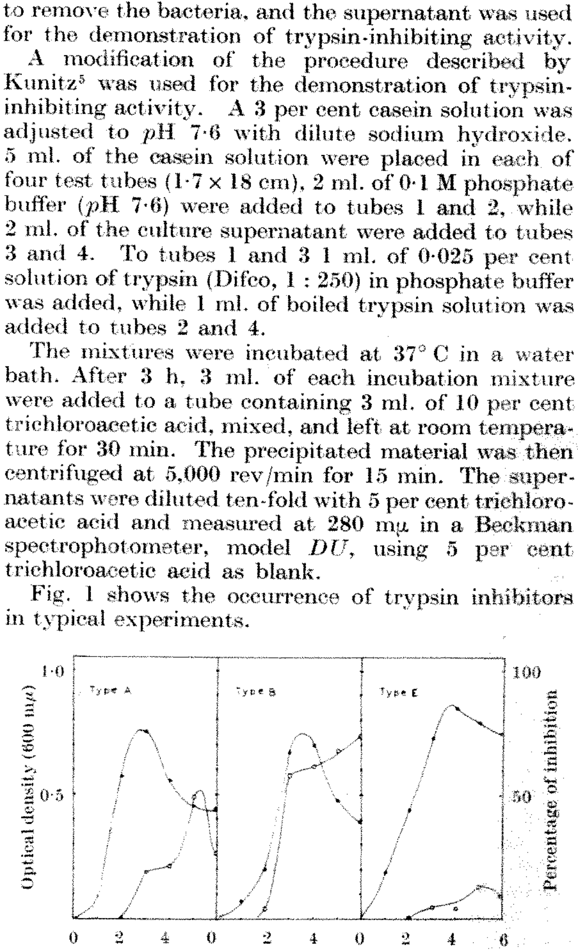

Fig. 1. Trypsin-inhibiting activity (open rings) compared with the bacterial growth (closed rings)

The trypsin-inhibiting activity varied greatly in different cultures of the same bacterial strain Under the conditions described the following ranges of maximum trypsin-inhibiting activities (per cent) were observed *Cl botulinum A* 13–51, *Cl botulinum B* 62–74, *Cl botulinum E* 5–35

Controls using sterile media incubated for the same period showed no trypsin-inhibiting activity

The trypsin inhibitor produced by the type *E* strain has been investigated to some extent The inhibitor was found to be easily dialysable, leaving the dialysis bag completely within 1 h when using a rotating technique The inhibitor also possesses great heat stability It may be kept at 100° C for 1–2 h without detectable loss in activity Later on the activity decreases slowly It has also been autoclaved at 120° C for 15 min without loss in activity

These results lead to the suggestion that the inhibitor is a small molecule, presumably organic in nature because ashing destroys the activity completely

VIROLOGY

A Simple Method for Total Particle Counts of Trachoma and Inclusion Blennorrhœa Viruses

DARK-GROUND illumination has been used to examine the elementary bodies of large viruses in stained and unstained preparations[1,2] We find that unstained crude suspensions of chick embryo yolk sacs infected with the viruses of trachoma and inclusion blennorrhœa, examined under dark-ground illumination, contain particulate host material which obscures the virus particles and which can be confused with them However, when such suspensions are dried, fixed and stained with Giemsa, many bright yellow-green particles are seen by dark-ground illumination, resembling elementary bodies stained with acridine orange and viewed by ultra-violet microscopy Their colour and intensity clearly distinguish them from background material, even if they are enveloped by it They resemble virus particles in size and shape, and their distribution in yolk sac smears is the same as that of the purple elementary bodies in films stained by Giemsa viewed by ordinary illumination, they are not present in smears of normal yolk sacs Our conclusion that these are virus particles is also supported by dark ground microscopy of inclusions found in HeLa cells infected with trachoma or inclusion blennorrhœa viruses[3] The inclusions contain numerous yellow-green particles similar to those in yolk sac smears and suspensions Large forms of virus are also recognizable, but are much less bright, and reddish in colour

We estimated the number of elementary bodies in suspensions of yolk sacs infected with these viruses Suspensions were made by shaking membranes for 1 min at room temperature with 0 5 per cent (w/v) trypsin in phosphate-buffered saline[4], removing the membrane and incubating the remaining suspension at 37° C for 30 min After removal of gross debris by low-speed centrifugation virus was deposited at 8,000*g* and resuspended in buffer to make a suspension containing the equivalent of 1 g yolk sac per 10 ml buffer A small amount of suspension was taken up in a 0 1 ml glass capillary tube ('Microcaps', Drummond Scientific Co), the length of the liquid column measured, a drop expelled on to a clean glass slide, and the length of the remaining column measured Since the capillary tube contains 0 1 ml and the bore is uniform, the volume of the drop placed on the slide could be calculated The drop was spread with a fine glass rod to give a thin circular film which was dried in air, fixed in absolute methyl alcohol for 10 min and stained for 30 min in Giemsa (Hopkins and Williams Ltd) diluted 1/10 in phosphate buffer *p*H 6 8 The film was then washed in buffer and dried at room temperature Elementary bodies were more easily seen when preparations were soaked in a mixture of 5 ml glacial acetic acid and 95 ml of chloroform after fixation and before staining To facilitate counting under dark ground illumination, an eye-piece stop was used, only those particles within the standard central area were counted, and at least 600 were counted in each drop The number of particles per ml of original suspension is

$$\frac{\text{No of particles counted} \times \text{area of drop}}{\begin{matrix}\text{No of fields}\\ \text{counted}\end{matrix} \times \begin{matrix}\text{volume of}\\ \text{drop}\end{matrix} \times \begin{matrix}\text{area of central}\\ \text{counting square}\end{matrix}}$$

the area of the drop being obtained from measurement of its diameter with calipers

If the distribution of virus particles within the drops conforms to Poisson's law, the variance of the distribution of the number of particles per field should equal the mean number per field In fact, the variance was 1 7–6 0 times greater than the mean, indicating that the particles were not distributed at random among different fields of the same drop This would arise if particles accumulated at the edge of the drop, or if they were clumped To reduce errors from these causes, drops were carefully spread before drying and consecutive fields across the drop were always counted Notwithstanding their non-random distribution in the drop, the number of particles estimated per drop was evidently proportional to the dilution of the suspension, since a similar count per ml of undiluted suspension was obtained by counting diluted or undiluted suspension (Table 1) Furthermore, the maximum variation in estimates of particle counts for seven drops of different sizes of the same suspension was only ± 20 per cent, for example, $2 9 \times 10^9 \pm 0 6 \times 10^9$

This technique is simple, quick and reproducible, and requires no special apparatus An advantage

Table 1 PARTICLE COUNTS ON YOLK SAC SUSPENSIONS OF TRACHOMA AND INCLUSION BLENNORRHŒA VIRUSES

	Virus strain	Dilution counted	Estimated No of particles per ml
Trachoma	*BOUR*[5]	1/1	$1 2 \times 10^9$
		1/5	$1 1 \times 10^9$
	ASGH[5]	1/1	$6 5 \times 10^8$
		1/5	$6 0 \times 10^8$
	*SA*2[6]	1/1	$1 0 \times 10^9$
		1/5	$1 3 \times 10^9$
	*TE*55[7]	1/1	$2 7 \times 10^7$
		1/4	$2 9 \times 10^7$
Inclusion blennorrhœa	*LB*1[8]	1/1	$5 0 \times 10^8$
		1/5	$5 5 \times 10^8$

over electron microscopy is that particles can be counted in infected yolk-sac suspensions without purification or concentration The relationship between particle counts and infectivity for chick embryos and HeLa cells is being investigated, using several strains of virus

Correlation between the Surface Structure of Viruses and Latency

By the use of DEAE-cellulose chromatography, we have endeavoured to obtain in their pure form various factors developed by adenoviruses during their propagation in tissue culture cells[1–4] HeLa or human amnion cells were inoculated with adenoviruses of types 1, 2, 3, 5, 7*a*, 9, 10, 11 and 15 On the 3rd–5th day the culture fluids were collected and were dialysed against 0 005 *M* borate buffer solution, *p*H 8 10 The dialysed fluid was then introduced into a DEAE-cellulose column (1 cm diam , 10 cm high) which was previously balanced by 0 005 *M* borate buffer solution, *p*H 8 10 Fractionation was carried out by adding 0 005 *M* borate buffer solution, *p*H 8 10, containing sodium chloride, to the column in linearly increasing concentrations of 0–0 8 *M* 5-ml fractions were collected and analysed with the view of detecting hæmagglutinins (by the reaction of hæmagglutination with the erythrocytes of rats and monkeys), also an early cytopathogenic factor[5,6], the complement-fixing antigen and an infectious virus.

Certain results obtained by these experiments are illustrated in Fig 1 Further detailed results will be published elsewhere

Attention is directed to the fact that adenoviruses of types 3, 7*a*, 9, 10 and 15, which cause acute diseases in human beings, can be eluted from the DEAE-cellulose column with smaller concentrations of sodium chloride (0 2–0 3 *M*) than types, 1, 2 and 5, which act as the latent ones eluted at 0 45 *M*–0 55 *M* sodium chloride The intermediate position is occupied by adenovirus, type 11 The observed regularity testifies to the difference in the structure of proteins which form the surface of adenoviruses, causing latent and acute infections respectively One may imagine that the proteins forming the membrane of latent adenoviruses contain a greater number of groups which are negatively charged at *p*H 8·10 than the proteins forming the surfaces of 'acute' adenoviruses

The characteristics instrumental in developing the latent nature of some infections caused by definite viruses are not known What is known, however, is that the viruses which cause latent infections sometimes lead to the development of acute diseases The viruses which are characterized by causing acute infections alone, never behave as the latent viruses It can therefore be assumed that the cause of latency lies not in the properties of the cells affected in this or that case but in the virus itself

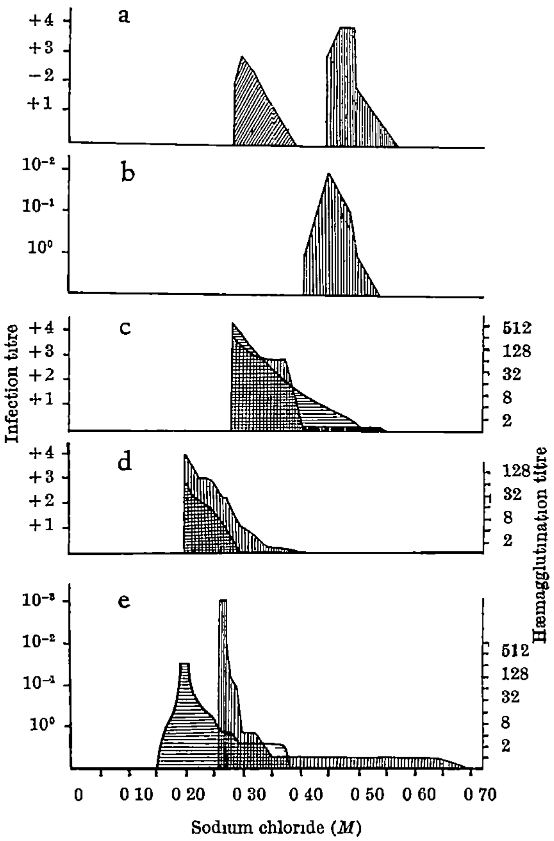

Fig 1 Fractionation of infected cultural fluids of adenoviruses of different serotypes on DEAE-cellulose Vertical shading, virus, horizontal shading, hæmagglutinin, oblique shading, early cylopathogenic factor *a*, Serotype 5 (similar to type 2), *b*, serotype 1, *c*, serotype 11, *d*, serotype 7*a* (similar to type 3), *e*, serotype 10 (similar to types 9 and 15)

In attempting to interpret the possible significance of this regularity we focused our attention on the ability of polyanions to hamper the course of the infectious process when tissue cultures were inoculated with polio virus[7] The question arises whether latent viruses do not contain similar polyanionic structures in their very elementary particles (unlike the 'acute' ones)—a phenomenon which is actually reflected in the greater number of anions on their surface Experiments in this direction are now in progress

FORTHCOMING EVENTS

Sunday, September 2—Wednesday, September 5

British Association for the Advancement of Science (at Manchester)—Continuation of 124th Annual Meeting

Sunday, September 2

At 11 a m.—Service in Manchester Cathedral Preacher The Lord Bishop of Manchester, the Right Reverend Dr W D L Greer, D D

Monday, September 3

At 10 a m —Prof F W Shotton, F R S "The Physical Background of Britain in the Pleistocene Period" (Presidential Address, Section C)

At 10 a m —Mr L P Kirwan "Nubia—an African Frontier Region" (Presidential Address, Section E)

At 10 a m —Mr W B Reddaway "The Economics of Underdeveloped Countries" (Presidential Address, Section F)

At 10 a m —Prof Bruce Pattison "English as an International Language" (Presidential Address, Section X)

At 8 p m —Prof Sir Alister Hardy, F R S "Man and the Beneficent Sea" (Evening Discourse)

Tuesday, September 4

At 10 a m —Dr M R House "Bursts in Evolution" (Darwin Lecture)

Wednesday, September 5

At 10 a m —Mr R A French "The Making of the Russian Landscape" (Lister Lecture)

Monday, September 3—Friday, September 7

International Conference on Water Pollution Research (at Church House, Westminster, London, S W 1)

Wednesday, September 5

Institute of Petroleum (at 61 New Cavendish Street, London, W 1), at 5 30 p m —Mr F S Beardmore and Mr W C G Kosters "Application of Sulpholane in Udex Units"

Monday, September 10—Friday, September 14

Institution of Gas Engineers, and the Institute of Fuel (at the White Rock Pavilion Main Hall, Hastings)—Conference on "Gasification Processes"

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned

Assistant Lecturer in Agricultural Economics—The Registrar, The University, Manchester 13 (September 8)

Experimental Officers or Senior Experimental Officers in the Polymer Science Group in the Chemistry Department of the Faculty of Science, to assist in the research work of the group under the general direction of Prof Gee—The Registrar, The University, Manchester 13 (September 8)

Lecturer or Assistant Lecturer (preferably with experience in teaching and research) in Zoology—Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S W 3 (September 10).

Research Assistant (with an honours degree in physics or mathematics or equivalent qualifications) to Prof N H March, to work on the density matrix theory of imperfection in metals—Prof N H March Department of Physics, The University, Sheffield 10 (September 10)

Scientific Officer (science graduate) to be the Senior Non-Medical Scientist dealing with the diagnostic work of a new Chromosome Laboratory which is to be opened early in 1963 by the United Sheffield Hospitals in conjunction with certain university departments—The Superintendent, The Children's Hospital, Sheffield 10 (September 10)

Assistant in Bacteriology—The Secretary, University of St Andrews, c/o Queen's College, Dundee (September 14)

Lecturer in Physics—The Registrar and Clerk to the Governors, College of Technology, Park Road, Portsmouth (September 14)

Assistant in the Department of Statistics—The Secretary, The University, Aberdeen (September 15)

Electronics Designer (with a degree in physics or electrical engineering, or a comparable qualification) in the Department of Chemistry, to collaborate with members of the teaching staff in designing and constructing electronic equipment to be used in research work in the Department—The Registrar, The University, Manchester 13 (September 15)

Research Assistant or Research Fellow in the Department of Livestock Husbandry within the Faculty of Rural Science, University of New England, Armidale, N S W , Australia, to study growth and type in beef cattle in relation to carcass attributes, undertake carcass appraisal studies, and to conduct research into aspects of meat quality—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W.1 (Australia and London, September 15).

Trainee Biochemist (with a degree or equivalent qualification in chemistry, with experience in, or wishing to take up, clinical biochemistry)—The Professor of Pathology, Cardiff Royal Infirmary, Cardiff (September 15)

Senior Lecturer and a Lecturer (preferably with qualifications in inorganic chemistry or biochemistry) in Chemistry, a Senior Lecturer and Lecturers in Physics, and Lecturers in Mathematics at Kwame Nkrumah University of Science and Technology—The Assistant Registrar, Kwame Nkrumah University of Science and Technology, 15 Gordon Square, London, W C 1 (September 17)

Lecturer (Grade II) in Veterinary Pathology in the Clinical Laboratory of the Veterinary Medicine Department at Langford (Bristol, 13 miles)—The Registrar and Secretary, The University, Bristol (September 21)

Lecturer in Pathology at the Western Infirmary—The Secretary of University Court, The University, Glasgow (September 22)

Senior Lecturer or Lecturer in Radiology at University College, Ibadan, Nigeria—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W C 1 (September 28)

Senior Lecturer (with an honours or higher degree in chemical engineering with research and teaching or industrial experience) in Chemical Engineering at the University of Cape Town—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1, and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (September 28)

Cotton Agronomist (with a university honours degree in science or agricultural science or equivalent qualifications, experience in organizing, carrying through and reporting on agronomic studies, and preferably with experience in the agronomy of cotton) at Kimberley Research Station, Division of Land Research and Regional Survey, C S I R O , to take part in the cotton research programme of the Station and undertake studies of an agronomic and plant nutritional nature—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W C 2, quoting Appointment No 620/28) (September 29)

Associate Professor in the School of Electrical Engineering, University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W C 2, and the Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, New South Wales Australia (September 30)

Senior Lecturer in Logic and Metaphysics in St Salvator's College—The Secretary, The University, College Gate, St Andrews (September 30)

Postdoctoral Fellows (2) (with at least a Ph D degree or equivalent, backed by research experience in the field of organic chemistry) in the Division of Protein Chemistry, C S I R O , Melbourne, one Fellow to study methods of synthesizing peptides, including oligomers, and the other Fellow to study the action of oxidizing agents on amino-acids, peptides and proteins—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W C 2, quoting Appointment No 462/161 (October 6)

Biochemistry Graduate (with experience in microbiology), for research work in chemotherapy—Dr G T Stewart, Department of Pathology, Queen Mary's Hospital for Children, Carshalton, Surrey

Entomologist (under 40) at the Royal Horticultural Society's Gardens, Wisley, Surrey, for duties principally advisory and instructional, but may include research work on insect pests affecting horticultural plants—The Secretary, Royal Horticultural Society, Vincent Square, London, S W 1, marking envelope "Confidential"

Geologist (Water Supply) (with an honours degree in geology or equivalent qualifications, and at least five years experience in water supply geology, including the electric logging of boreholes) in Northern Nigeria, to supervise the water supply exploration drilling projects and the training of Nigerian staff—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S W 1, quoting Ref RC 254/105/01.

Hospital Physicist (Basic grade) (honours physics graduate)—Dr B Levin, Pathology Department, Queen Elizabeth Hospital for Children, Hackney Road, London, E 2

Lecturer or Senior Lecturer (with good academic qualifications and preferably research experience to doctorate level or equivalent) in the Department of Electrical Engineering—Dr J H Calderwood, Royal College of Advanced Technology, Salford

Lecturer (with an honours degree in pharmacy or equivalent qualification, experience in research methods, and preferably industrial experience) in Pharmaceutics, and a Lecturer (with an honours degree in science or pharmacy, with special qualifications and research experience in pharmacology) in Pharmacology—The Secretary, Royal College of Science and Technology, George Street, Glasgow, C 1

Mathematician (well qualified) in the Mathematical Department—The High Master, Manchester Grammar School, Manchester 13

Physical Chemists or Physicists (with a Ph D and preferably in the age group 24–28) in the London Research Station and in the Basic Research Group, both located at Fulham, for original research into gas/solid catalysis and experimental methods for the examination of catalysts—The Staff Controller, North Thames Gas Board, 30 Kensington Church Street, London, W 8, quoting Ref NE/1181

Professor (normally national of the United Kingdom or the Republic of Ireland, at least five years university teaching experience or five years relevant industrial experience, and preferably a Ph D) of Electrical Engineering (Power) at the Middle East Technical University, Ankara—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S W 1, quoting Ref RC 203/152/03

Research Assistant (with a degree in botany, diploma in food science or equivalent qualifications) in the Potato Branch, for work on quality in potatoes—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge

Scientific Information Officer (Abstractor) (with a degree in agriculture or natural science, and able to translate from German)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire

Technician (with biochemical experience), for research on enzymes and metabolites of neurological interest—The Secretary, Institute of Neurology, The National Hospital , Queen Square, London, W C 1

TEMPORARY RESEARCH ASSISTANT (with a degree in chemistry or biochemistry), for the staff of the Low Temperature Research Station, Cambridge, but seconded to the Department of Chemistry, Royal Holloway College (University of London), Englefield Green, Surrey, to work on phenolic metabolism in plants—The Secretary, Low Temperature Research Station, Downing Street, Cambridge, quoting Ref RHC

£500 A YEAR TAX FREE FOR YOUR FAMILY

The Equitable offers you a special plan to protect your family's future at the lowest possible cost Should you die within a period of 20 years your dependants will receive £500 a year tax free for the balance of the period

You only pay premiums for 15 years and if you are 29 now the cost is as little as £18 5 0 a year—about 7/- a week The premiums for larger benefits are in proportion

The Equitable offers attractive terms because it has no shareholders to take any part of the profits and pays no commission for the introduction of business

THE EQUITABLE
FOR A BETTER DEAL

The EQUITABLE Life Assurance Society,

'AGLA' BRAND

MICROMETER SYRINGE

A precision instrument capable of measuring very small volumes of fluid with an accuracy of ± 0·00005 ml.

BURROUGHS WELLCOME & CO.
(THE WELLCOME FOUNDATION LTD)
LONDON

APPOINTMENTS VACANT

CLASSIFIED ADVERTISEMENTS are charged at 12s for the first line and 6s per line thereafter Lines in capitals or containing words in capitals 12s per line. Semi-displayed £4 16s per single column inch Colour (orange) £15 extra 1s is charged for the re-direction of replies to advertisements with a box number

ADVERTISEMENTS SHOULD BE ADDRESSED TO T G Scott and Son, Limited, 1 Clement's Inn, Strand, London, W C 2 Telephone HOLborn 4743 Telegrams Textualist, Estrand, London

SOUTH AUSTRALIAN INSTITUTE OF TECHNOLOGY

NORTH TERRACE, ADELAIDE

Applications are invited from suitably qualified people for the following three appointments, each will carry the status and salary of a professor (£4,250 in South Australia)

1 Head of the School of Engineering
2 Head of the School of Chemical Technology and Metallurgy
3 Head of the School of Applied Physics

Each of these Heads will also have the status of Assistant Director The Assistant Director (Engineering) will control the three departments, Civil, Electrical and Mechanical The Assistant Director (Chemical Technology and Metallurgy) will be responsible for the four divisions of Pure Chemistry, Applied Chemistry, Primary Metallurgy and Secondary Metallurgy The Assistant Director (Applied Physics) will be responsible for the Department of Mathematics and Physics and the Department of Electronic Engineering

The Institute provides the following courses of study For Bachelor Degrees of the University of Adelaide in Civil, Electrical and Mechanical Engineering, Surveying, Chemical Technology, Primary Metallurgy and Secondary Metallurgy, Electronic Engineering and Building Technology A degree course in Industrial Physics is shortly to be instituted Diploma Courses in Accountancy, Architecture, Business Administration, Home Science, Quantity Surveying and Town Planning Also a wide range of Ordinary and Higher Certificate and Technicians' Courses Individual student enrolments are approximately 12,000 including both part-time and full-time students

The Institute is expanding rapidly in response to the very great development of secondary industry in South Australia Long service leave and superannuation benefits are available in addition to the customary annual leave and sick leave If living out of the State or country, the successful applicant would be assisted in meeting reasonable travelling expenses He should be prepared to commence duty not later than January 1, 1963

Further particulars may be obtained from the Director, to whom applications should be addressed so as to reach him not later than September 1, 1962 Applicants from the United Kingdom may obtain particulars from the Agent-General for South Australia, 50 Strand, London, W C 2

BOARD OF GOVERNORS

HAMMERSMITH AND ST MARK'S HOSPITALS

DUCANE ROAD, LONDON, W 12

Applications invited for the appointment of Senior Physicist at Hammersmith Hospital, to be responsible for clinical physics on 8 MeV linear accelerator used for X-ray and electron therapy Opportunities for research and teaching in lively atmosphere Hospital experience preferred but other postgraduate experience, particularly electronic, welcomed

Further details from Head of Department Inclusive salary scale £1,305 to £1,755 per annum Detailed applications, naming two referees, to Secretary, Board of Governors by September 15

BAKELITE LIMITED OFFER AN INTERESTING position in their Patents Department, Birmingham, to a Chemist with an honours degree The work is primarily concerned with patent information and its significance in relation to the Company's production, sales and development activities Full training will be given The working conditions are congenial and a favourable Staff Pension Scheme is in operation — Application should be made to the Personnel Manager, Bakelite Limited, Redfern Road, Tyseley, Birmingham, 11

UNIVERSITY OF NEW ENGLAND

ARMIDALE, NEW SOUTH WALES

LABORATORY TECHNICIAN AND/OR RESEARCH ASSISTANT IN AGRONOMY

Applications are called for the above named vacancies in the Department of Agronomy within the School of Rural Science The appointee will be employed on a research programme dealing with aspects of pasture plant physiology Commencing salary will be determined according to qualifications and experience within the range of £A 966 to £A 1 380 for a Laboratory Technician and within the range of £A 845 by £A 65 to £A 1,360 for a Research Assistant A cost of living adjustment at present amounting to £A 42 per annum is also payable in the case of the Research Assistant The appointee will be a graduate in science (botany), rural science or agricultural science and will be encouraged to undertake studies for a higher degree for which tuition fees will be remitted

Applications, in duplicate, should be forwarded to reach the undersigned no later than September 28, 1962, and should include details of qualifications and experience, the names of two referees and a recent photograph Applicants from the United Kingdom should forward an additional copy of their application to the Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S W 1, by the same date

T C LAMBLE,
Registrar

University of New England,
Armidale, New South Wales, Australia

UNIVERSITY OF MANCHESTER

Applications are invited for appointment a Electronics Designer in the Department o Chemistry The successful candidate would b required to collaborate with members of th teaching staff in designing and constructing electronic equipment to be used in research work i the Department Candidates should have a degree in physics or electrical engineering, or comparable qualification Appointment would b in the grade of Experimental Officer or Senio Experimental Officer Salary range £800 by £3 to £890 by £40 to £1,050 per annum (Experimental Officer), and £1,150 by £50 to £1,350 (meri bar-line) by £50 to £1,650 (Senior Experimenta Officer) The initial salary will be according t qualifications and experience Contributory superannuation scheme

Applications should be sent not later tha September 15, 1962, to the Registrar, the University, Manchester, 13, from whom further particulars and forms of application may b obtained

UNIVERSITY COLLEGE HOSPITAL

GOWER STREET, LONDON, W C 1

Basic Grade Physicist required Radiological physics and the application of physics to a wide range of medical problems Good workshop and technical assistance Facilities for individual research

Applications, with names of two referees, to Administrator and Secretary

THE INTERNATIONAL NICKEL COMPANY (MOND) LIMITED

requires a young male or female

ABSTRACTOR/TECHNICAL WRITER

to assist in the preparation of publications covering metallurgical literature relevant to the Company's activities Ability to write concise, clear English is essential for the post, and a knowledge of German and French is desirable

Applications, giving full details, should be addressed to

**The Manager,
General Division, Development and Research Dept.,
The International Nickel Company (Mond) Limited,
Thames House, Millbank, London, S W.1
Mark envelope 'Confidential M 12'**

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF PROTEIN CHEMISTRY

POST-DOCTORAL FELLOWSHIPS IN ORGANIC CHEMISTRY

The Organization's Division of Protein Chemistry located in Melbourne, Victoria, invites applications from graduates in Organic Chemistry for two Post-Doctoral Fellowships Applicants should have at least a Ph D degree or its equivalent backed by research experience in the field of organic chemistry

One Fellow will study methods of synthesizing peptides including oligomers The other Fellow will be appointed to study the action of oxidizing agents on amino acids, peptides and proteins Both appointees will join the group of organic chemists in this Division who are already studying peptide synthesis, the photo-degradation of cystine, tryptophane and related peptides, reactions of Bunte salts, chemical modification of proteins, etc The work would be integrated with other chemical, physico-chemical and biophysical studies on protein structure and reactivity in the Division

The Fellowships are initially offered for a period of three years

Salary Commensurate with qualifications and experience, minimum salary offered £A 1,750 per annum up to a maximum of £A 2,751 per annum

Salary for women will be £A 188 per annum less than corresponding rate for men

Fares paid for the appointee and his dependent family and return fares to point of origin paid for an appointee who, by arrangement, accepts appointment for a fixed term Further particulars of conditions, etc, supplied on application to

Mr P F Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W C 2,

to whom applications (quoting Appointment No 462/161) should be addressed by October 6, 1962

THE FUTURE FOR BRITISH TELEVISION AND BROADCASTING

ALTHOUGH the Report of the Pilkington Committee on Broadcasting[*] deals with several matters of direct concern to the scientist, which are summarized elsewhere (see p 949 of this issue), the report is of primary importance as a social document As the Committee itself points out, broadcasting is by common consent of profound social significance, and the considerations which have shaped the exercise by successive Governments of their control of broadcasting have been, above all, social considerations Moreover, a control which derives from the need to ensure the orderly use of scarce frequencies, and is thus technical in its purpose, is applied in the United Kingdom for reasons which are essentially social

This point can scarcely be overstressed, for it has determined fundamentally the outlook of the Pilkington Committee itself and the extent to which the Government in its Memorandum[†] on the Report accepted the Committee's recommendation on one hand and on the other deferred some for further consideration In fact, so far as television is concerned, since the Television Advisory Committee was concerned only with technical factors affecting a change in line-definition standards, it fell to the Pilkington Committee to examine the social and economic factors It may be regarded as having given insufficient weight to the effect of competition on the British Broadcasting Corporation, and it has been suggested that it might have sought more convincing or scientific evidence on certain matters Despite the presence of two scientists among its members, the Committee was not, however, a scientific or a technical body It was chosen to provide a representative sector of intelligent lay opinion, and it may be surmised that its advice would have been regarded as suspect could it have been described as in any sense expert or highbrow Furthermore, the Committee emphasizes at the start of the Report that there is so far very little conclusive evidence on the effects of television on values and moral attitudes There is no attempt in the Report to overstate a case or to suggest that trends and possible dangers to which a wide range of witnesses directed attention was proved or were as yet more than contingencies to which regard should be paid by responsible authorities

This has been so ignored in much of the early criticism and uproar over the Report that its significance and true character can scarcely be appreciated without some summary of the Committee's views on the purposes of broadcasting This chapter, which follows on a general survey of the present position, is basic to the Committee's appraisal of the services now provided and its proposals for the future In the light of this chapter it can best be seen how far the Government proposals outlined in the White Paper are in harmony with the spirit of the Report It should be remembered, moreover, that not only did the Committee make its examination at a time when important developments are impending, and when the limited frequency space available makes it essential, that what is available should be used to the best advantage it was also conducting the first examination of a broadcasting authority other than the B B C , of broadcasting services operating under conditions of competition, and of broadcasting when television has become the major force

This chapter, then, is the real core of the Report, and at the start the Committee notes that neither the British Broadcasting Corporation nor the Independent Television Authority attaches any significance to the difference in wording or to the difference in order in which the three elements of information, education and entertainment are placed in the Corporation's Charter and in the Television Act The unanimous opinion was expressed to the Committee that no written formula for good broadcasting is possible it is a practice not a prescription, and the Committee, while setting its standards high, took the view that a service of broadcasting should be judged not by the stated aims of the broadcasters but by their achievements, and that the structure of their organizations should be examined in the light of those achievements Broadcasting is more nearly an art than an exact science, dealing in tastes and values, without being precisely definable, and the test of success is the programmes

In the main, submissions made to the Committee about sound broadcasting expressed satisfaction with the service Comment, critical or otherwise, was relatively lacking, and there seems to be no significant failure to realize the purposes of broadcasting For television, on the other hand, there was a large volume of sharply critical submissions, and those from people and organizations as viewers showed much disquiet and dissatisfaction The disquiet derived from the view that the power of the medium to influence and persuade is universal, and from a strong feeling, amounting often to a conviction, that the power was often being so used as to suggest a lack of awareness of, or concern about, the consequences Those who represented this view saw television as one of the major long-term factors that would shape the moral and mental attitudes, the values of our society Dissatisfaction derived from the view that there was something lacking in the programmes as such, possibly of items of one kind or another, or a more general lack of quality

It was not suggested that the picture was uniformly black or grey, but the submissions left no impression that there was little wrong with television

---

[*] *Report of the Committee on Broadcasting,* 1960 Pp xii+342 (Cmnd 1753) (London H M Stationery Office, 1962) 18s net

[†] *Broadcasting Memorandum on the Report of the Committee on Broadcasting* 1960 Pp 12 (Cmnd 1770) (London H M Stationery Office, 1962 1s 3d net

Admittedly this is not evidence, and the Committee does not suggest that this assessment of the power of the medium is proved Nevertheless, those who work professionally in this sphere held that what evidence there was showed that there was an effect, perhaps persistent, apparently imperceptible but in the end prevailing It may be that in this sphere cause and effect can never be absolutely demonstrable, but the Committee is clearly right to hold that there must be a presumption one way or the other on which to found policies for the conduct of the services, and against which to measure the responsibilities of those who provide them Whatever difficulty may arise in giving it practical expression, the Committee would have been socially irresponsible had it reached any other conclusion in the face of the available evidence than that television is and will be a main factor in influencing the values and moral standards of our society

By its nature, broadcasting must be in a constant and sensitive relation with the moral condition of society Broadcasters cannot evade the consequent responsibility, either because the effect has not been conclusively proved or because of the difficulties that arise in offering a wide range of choice to the public Here again the Pilkington Committee puts the issue fairly and sensibly "To give the public what it wants" is a misleading phrase and should only be used in the sense that what the public wants and what it has the right to get is the freedom to choose from the widest possible range of programme matter Anything less is deprivation

Here particularly, the Report has been widely misrepresented The Committee reiterates that the broadcasting authorities have a duty in so far that they should keep themselves aware of the public's tastes and attitudes as they now are and in all their variety Furthermore, they should respect the public's right to choose from the widest possible range of subject-matter and/or to enlarge worth-while experiences In actual fact the Committee found that the antithesis "broadcasting should give the public what it wants, and not what someone thinks is good for the public" was regarded as a gross over-simplification of a complex and continuing problem No broadcasting authority accepted either of the two extremes, all saw their policies as lying between them There were differences of emphasis and there is obviously a very wide range of possibilities between the two extremes No one, however, argued against any departure from "giving the public what it wants" on the grounds that it implied a measure, however small, of 'paternalism' and was, for reasons of democratic doctrine, inadmissible On the contrary, all accepted that there was a responsibility to help towards a broadening and deepening of public taste

Nevertheless, the Pilkington Committee found reason for supposing that in television the purposes of broadcasting were to a material extent not being realized, and specifically it urges the responsibility of broadcasting, and especially television, to focus attention on the growing points of experience These are usually most significant, and at these points the challenges to existing assumptions and beliefs are made, the claims to new knowledge and new awareness stated If our society is to respond to the challenges and to judge the claims, they must be put before it All broadcasting, and television especially, must be ready and anxious to experiment, to show the new and unusual, to give a hearing to dissent Here, broadcasting must be most willing to make mistakes, for if it does not, it will make no discoveries"

For that passage alone the Pilkington Committee has earned the respect of the scientist, and its whole spirit makes nonsense of much of the attack that was immediately launched on the Report It provided a firm basis for Lord Hailsham's appeal in opening the House of Lords debate on July 18 to discard the generalizing about paternalism, commercialism, monopoly and free-enterprise which has so long dominated discussion of this subject and to seek an agreed broadcasting policy based on technical necessity and practical politics Lord Hailsham agreed that the unease emphasized by the Committee could not be dismissed as contemptible or ridiculous Moreover, apart from his firm warning to the programme companies about profits, he fully supported the thesis that the state of public morals and the standards of taste in public entertainment could never be a matter of indifference to patriotic men and women and are not necessarily adequately catered for by purely commercial considerations

It is unnecessary to pursue further for the present purpose the Pilkington Committee's appraisal of either the broadcasting or the television services in order to appreciate the significance of the recommendations of its Report It will suffice to reiterate the major elements which in its judgment, good television broadcasting should comprise First, programme planning and content must respect the right of the public to choose from among the widest possible range of subject-matter Secondly, in every part of this wide range, approach and presentation must be of high quality Lastly, and of overriding importance those who handle this powerful medium must be animated by a sense of its power to influence values and moral standards and of its capacity for enriching the lives of all of us The broadcasting authorities must care about public tastes and attitudes, and must keep aware of them, and of their capacity to change and develop

The Committee's recommendations for British television number 120 and are summarized under organization, existing services, new services and technical It proposes no change in the arrangements for the discharge of the Government's ultimate responsibility for the social consequences of broadcasting, and the Postmaster-General should continue to be responsible for the exercise of the Government's powers under the general authority and direction of the Prime Minister In accepting this recommendation in the White Paper, the Government states that there will be no separate Minister for Broadcasting, and no major change is proposed in the powers of the Government, which will remain largely as at present. Furthermore, in effect, the Committee's recommendation that there should be unremitting observance of the fundamental independence of the broadcasting authorities from Government intervention in the day-to-day management of their affairs, including programme content, is also accepted, though changes may be proposed in the new Charter and Act The Committee also suggests that the presentation to Parliament of the annual reports of the broadcasting authorities should be the occasion for an explanation of policy and for a revealing examination of criticisms

The Committee also recommends continuance of the power of the Postmaster-General to veto any particular broadcast or class of broadcast, and that the Independent Television Authority should be empowered to announce the use of this veto. It suggests that discussion between the broadcasting authorities and senior officials of the Post Office on the appointment or reappointment by the Government of governors of the British Broadcasting Corporation or the Independent Television Authority, should be conducted on behalf of the broadcasting authority by its Chairman, and that the Postmaster-General should continue to prescribe the hours of broadcasting It emphasizes that there should be no marked disparity between the number of hours of television for which each of the two broadcasting organizations is allowed to broadcast on any one service

On these further recommendations regarding the powers and duties of the Government the White Paper makes no comment. Those relating to the British Broadcasting Corporation are largely accepted. The Corporation will continue to be constituted by Royal Charter, and the view that the Charter (and also the Television Act) should be renewed for 12 years from July 30, 1964, is accepted The Government also agrees that where it is possible at Royal and State occasions of national interest for only one camera team to be present the Corporation should have the right and duty of undertaking the broadcast The Government also accepts the Committee's proposals on the Chairman and Governors of the Corporation, but does not propose to make ability to speak Welsh an absolute qualification for the National Governor for Wales It also agrees that the appointment of the Corporation's General Advisory Council, but not its size, which should vary between eight and twelve members, should continue to be prescribed by the Charter It accepts the recommendation that the Corporation's National Broadcasting Councils for Scotland and Wales (and for Northern Ireland, if established) should exercise the same powers in regard to the content of television services as they already do for sound It commends to the Corporation the Committee's comments about an advisory committee on scientific programmes, but the recommendation regarding the Corporation's Central Religious Advisory Committee is for discussion with religious bodies and leaders.

On finance, the Pilkington Committee recommends that the British Broadcasting Corporation should continue to be financed out of licence revenue, and only out of licence revenue, and while no material change is recommended in the principles governing the licence fee system, or in the arrangement whereby the proportion of net licence revenue payable to the Corporation is negotiated with the Paymaster-General and the Treasury, the Charter should be amended to empower the Corporation to borrow money up to a limit of £10 million This recommendation is accepted by the Government, but beyond accepting its responsibility to see that the Corporation can secure sufficient revenue to finance adequate services, the Government in the White Paper makes no comment on finance, particularly on the Committee's view that a fee of £6 annually for a combined sound and television licence would be reasonable

On independent television the Report recommends major changes in its constitution and organization The Independent Television Authority should plan programming and sell advertising time, the programme companies producing and selling to the Authority programme items for inclusion in the planned programme The Authority, after making provision for reserves, should pay any surplus revenue to the Exchequer On these proposals the Government has reserved its decision, and wishes first to be satisfied that any new structure will remedy the defects it is intended to overcome, without throwing up equally serious difficulties of its own or depriving the existing system of those features for which it can fairly claim credit This is a reasonable view, and the White Paper makes it the key point for public (including Parliamentary) discussion of which the Government promises to take full account

Meanwhile, the Government has accepted some minor recommendations relating to independent television It agrees that the Authority should set up a Committee for Wales to advise on the general conduct of independent television in Wales as it has done for Scotland and Northern Ireland, but that this does not require statutory force Decision is reserved on the recommendation that the Authority should be relieved of its statutory obligation to appoint an Advertising Advisory Committee and a Children's Advisory Committee as too closely connected with the question of the future structure of independent television The Government accepts the recommendations that advertising magazines should be prohibited, and that the maximum and average amounts of advertising time should be prescribed by the Authority and not by legislation It proposes to discuss with the Authority the question of a possible change in the minimum interval of time between breaks for the insertion of advertisements, as well as the permissible content of advertisements and the formulation of the Authority's code of principles for television advertising There is no comment on the recommendations that the British Broadcasting Corporation should continue to engage in research into the scientific and technical aspects of broadcasting, and in continuous and perceptive audience research, giving both areas of research the resources they reasonably need, or that the Independent Television Authority, on the other hand, should engage in, or commission, research and development work, including continuing and perceptive audience research, the cost of which should be an admissible charge on revenue In the House of Lords debate it was suggested that the Government should establish a central fund for research and development in television, possibly from the Authority's surplus revenue from the sale of advertising time, and the idea of centralized or co-operative research in this field at least calls for consideration

The Pilkington Committee takes the view that no additional national sound broadcasting services are needed, although it recommends that the two broadcasting organizations should give special attention to the needs of the deaf With this view the Government agrees The Committee recommends rejection of the proposals for separate, independent Scottish and Welsh Broadcasting Corporations, but recommends the planning of one service only of local sound broadcasting, not financed from advertising revenue but from licence revenue, provided by the British Broadcasting Corporation and planned to serve the largest possible number of distinctive communities that technical considerations will permit Within these local sound services it suggests that the Corporation and the motoring organizations should conduct an experiment of broadcasting information to motorists on road and traffic conditions While the Government argues that the justification for local sound broadcasting would be the provision of a service genuinely 'local' in character, it questions the existence as yet of any such demand and proposes to take note of public reaction before deciding The Pilkington Committee itself recommends that the completion of the transmission coverage, on very-high-frequencies, of the Corporation's three national sound services should take precedence

Otherwise, on new services the Committee recommends rejection of the proposals to create an additional public corporation to provide an additional television service, or that an additional television programme should be provided jointly by the British Broadcasting Corporation and independent television Instead, it recommends that the Corporation should provide the next additional television programme and should be authorized to do so as soon as possible, and this the Government proposes to do, but it does not commit itself to the further recommendation that no additional television service should be provided by independent television before the authority is reconstituted and reorganized Meanwhile, the new programme will be on 625 lines in U H F , starting in London by mid-1964 and extending to the rest of Britain as rapidly as possible thereafter The Pilkington Committee recommends rejection of the proposals for a service of sponsored television, and no service of subscription television should be authorized

Technically, as noted elsewhere, it recommends that the line definition standard in use in the United Kingdom should be changed from 405 to 625, and that a compatible service of colour television should be introduced on the 625-line definition standard The Government appears to accept the Committee's view that an ultimate pattern of six programmes is required and that two more programmes should be provided in the next four years The new programmes in U H F will be on 625 lines from the start, although the present services will continue on 405 lines for some considerable time The Government accepts the Committee's view that the first call on the unallotted frequencies in Band III should be to enable the Corporation to separate its service to Wales from that to the English Regions It proposes to authorize the Corporation to proceed as early as possible with the provision of a new transmitter to give a distinctively Welsh service to South Wales Stations to serve North-East Wales and South-West Scotland may also be required, and it is also proposed to authorize the Corporation to start transmitting some programmes in colour as part of their second programme, and similarly for any future independent television programme although the system of transmission is not yet finally decided Decision on pay-television is reserved and the Government does not accept the Committee's rejection of television for public showing, suggesting that for the time being applications to provide such a service should be considered on their merits Party political broadcasting is to be discussed, in the light of the Committee's comments, with the political parties and the broadcasting authorities

The Government has thus manifestly adopted a considerable number of the conclusions of the Pilkington Committee, some of which are far from being minor ones, and is taking the appropriate action On others, as on local broadcasting, its own assessment of the situation is reasonable enough Beyond this, as the Bishop of Leicester remarked in the House of Lords on July 19, the Report has made it more difficult for any Government to ignore or repudiate its responsibility in those realms of human life where moral attitudes are formed and developed Government and Opposition alike are clearly hesitant in facing the financial issues and reluctant to adopt the recommendation for an increase in the licence fee to £6, though this seems both the most salutary course and one that compares well with what is charged in most West and Northern European countries. There are difficulties, though not necessarily insuperable, in other methods of finance, such as subsidy, if political pressure or the suspicion of political pressure is to be avoided, and even if this risk could be avoided by some system of grants over a term of years, while even the proposed increase would leave the fee lower than that of so many other countries, the straightforward increase seems the more desirable method

The real question remains the future organization of independent television Here, the White Paper is scarcely convincing that the Government has accepted the essence of the Committee's conclusion. Although the Government has decided so promptly to give the third channel at once to the British Broadcasting Corporation, to give independent television also a new channel in advance of re-organization or reconstitution might defeat the whole purpose of the Pilkington proposals On this the Postmaster-General was perhaps a little more reassuring in the debate in the House of Commons on July 31 than is the White Paper itself Meanwhile, the change-over itself from 405 to 625 lines involves problems enough, and although the White Paper gives no details it seems that the Government's policy is reasonable. The creation of a national network of U.H.F. stations is a major undertaking and while existing V.H.F. sites and masts will be used to the fullest possible extent, many new U.H.F. stations must be built. Further, as is pointed out in the *BBC Record* for June, much more care has to be taken in locating the receiving aerial, which by and large will itself be more costly. In most locations it will be necessary, first, to have an outside aerial and secondly to have an aerial of high-gain costing appreciably more than the indoor and outdoor aerials which are often adequate for Bands I and III. The method by which the change-over is best affected is a technical problem which has still to be examined fully, and if the adoption by the Government of the Pilkington Committee's recommendation in this field has made this a matter of some urgency it is as well that the user should appreciate that the cost of technical advance is not something which should be borne entirely by the State. It is right and salutary that some of the charge should fall on those who immediately benefit by it, and that in itself should help to keep the further discussion of the organization of television and sound broadcasting on sensible and realistic lines attuned to technical and social needs rather than political prejudices.

METAPHYSICS FOR EMPIRICISTS

Foundations of Empiricism

By James K. Feibleman. Pp. xi+389. (The Hague: Martinus Nijhoff, 1962.) 27 guilders.

THIS book is very ably written. The author has a long list of philosophical works to his credit, dealing with almost every aspect of the theory of knowledge, including the social sciences. There are seven parts: categorematics, axiomatics, systemics, ethics, practices, historics and epistemics. Such a formal framework keeps the argument neat and tidy. The aim throughout is to regenerate metaphysics in a way calculated to make the subject amenable to empiricism. In other words, the metaphysician should be constrained within the boundaries of logic and fact. It is true that there have been several varieties of this discipline in the past, on the whole unsuitable, or at least unhelpful, for an age of advancing scientific enterprise. A writer of Thomist sympathies, Fr. F. C. Copleston, has remarked that metaphysics must come to terms with empiricism. The changeless view of being, as we should say, "independent of a mechanism", is too uncritical, and it is no wonder that scientists have found it unacceptable. By a deliberate search for a finite metaphysics we are invited to overcome this defect.

So far so good. Perhaps subject and object have become out of step in the course of time, with the former predominant. It is maintained that subjectivism, Greek as it was, represented at least a partial decline from the summit of Hellenic philosophy. There is no reasonable doubt that such is a true reading of history. What is odd, is that the author should belabour the theologians for their handling of these matters. Nobody to-day would try to justify the unhappy events of a century ago, for they are over and done with: so much so, in fact, that no reputable scholar is likely to make the mistake of asserting that theoretical physics can be used as a prop for religion. (Symbolic logic may possibly capture ethics and æsthetics, but that is something quite different.)

All this, however, is not to deny a place for a further plane of discourse whereon epistemic conditions are "wholly other", and to which its own metaphysics may apply. They should indeed be humble and searching. As regards the Metaphysical Society of 1869, the author has presumably read the penetrating record by his fellow-countryman, Prof. A. W. Brown (1947), of this phase of thought, remembering that the original title was "Theological" and not "Metaphysical". The whole purpose of the change was to make for obvious impartiality.

The association of metaphysics with some kind of transcendentalism is largely a matter of language, and one can sympathize with the writer in his desire to reduce the number of assumptions supporting an objective ontology.

The interplay of belief and reason goes on. The West has inherited the Augustinian "*Credo ut intelligam*", and passed it on through Anselm and Duns Scotus. Without rejecting it, there is an honoured place awaiting the empirical metaphysics for which this volume so clearly strives. F. I. G. RAWLINS

THE M.K.S. SYSTEM AND ELECTRICAL THEORY

Electrical Theory on the Giorgi System

By P. Cornelius. Translated from the third Dutch edition by Dr. L. J. Jolley. Pp. x+187. (London: Cleaver-Hume Press, Ltd., 1961.) 32*s*. net.

PUBLICATIONS emanating from the Philips Research Laboratories have a high reputation, and this English translation of a book which has reached a third edition on the Continent will be read with great interest throughout Great Britain.

The battle for the M.K.S. system advocated by Giorgi is almost won. There can be few electrical engineers remaining who are not convinced of its merits and the objections of physicists to this system do not appear to be insuperable. Advocacy of the M.K.S. system is, however, only a minor purpose of the author, whose main objective appears to be the expounding of electrical theory up to quite advanced levels with a minimum use of mathematics.

His starting point is Ohm's law, and one suspects that he would have preferred both the volt and the ampere to be regarded as fundamental units, dispensing with one of the mechanical units. From this familiar law he develops the ideas of electric field strength and current density as vectors, passing easily from there to the concepts of electric and magnetic flux. In the space of 45 pages electrical theory is developed up to Maxwell's laws and divergence and curl are introduced so naturally that the least mathematical of his readers should have no difficulty in following his argument.

Mechanical forces are not introduced until the second chapter, but this inversion of the normal order of developing electrical theory is not without its difficulties. In establishing Ohm's law the author uses mechanical forces to detect and measure both voltage and current. The power consumed in a resistance is stated as an axiom, since the real nature and dimensions of voltage and current are not revealed until much later. The book is indeed more valuable for the technologist wishing to tie up loose ends of his electrical knowledge than it would be for the young student aiming to grasp the fundamentals of his subject. For him, Coulomb's law of forces between electric charges remains the natural starting point of his subject. The best method of introducing the concept of the magnetic field is perhaps more controversial; but it is doubtful if many teachers of electrical engineering will be prepared to relegate mechanical forces to the secondary position which they occupy in this book.

About half the book is devoted to an exposition of selected problems. The author's self-denying ordinance with regard to the use of mathematics prevents the study of these problems to any great depth, but the reader's interest is maintained throughout.

Electrical engineers in Britain should be grateful to Dr. Jolley for the most attractive translation of this work and to the Cleaver-Hume Press for the publication of it. No misprints were found, the contrast of print and paper are excellent and the diagrams clear.

A. H. M. ARNOLD

AN ATLAS FOR SPECTROCHEMICAL ANALYSIS

Atlas of Analysis Lines

Prepared by Halina Jaffe, with the technical assistance of N. Turkeltaub. Pp. 13 + 50 plates. (London: Hilger and Watts, Ltd., 1962.) £26 5s.

THE publication by Halina Jaffe presents the enlarged iron spectrum in three ranges, 2478 Å – 3499 Å, 3324 Å – 8943 Å and 3981 Å – 5350 Å, the last range being taken with glass optics. The spectra are presented on 50 cards, the iron arc spectrum being in the centre, the persistent lines of 69 elements having been added manually on either side of it.

In assessing the value of this *Atlas*, comparison will naturally be made with its well-known predecessor by Gatterer and Junkes, and also with others that have appeared from time to time in text-books on the subject, of which that by Brode (*Chemical Spectroscopy*) is probably the most widely used. Jaffe's *Atlas* has advantages over either of these but at the same time is not devoid of its own limitations.

The charts are of handy size and are particularly suitable for use with Hilger instruments. The author emphasizes this, and specifies type and number of spectrograph and projector used in the production of the charts; using other projectors by the same maker, however, they are somewhat less convenient. The arc lines appear as black lines on a white ground as in a normal spectrogram, at a degree of enlargement well chosen for the purpose. Two tables are included which list the most persistent lines of the 69 elements which have been included in the charts, in order of element and in order of wave-length, respectively. These are not intended to be comprehensive wave-length tables; in fact only two lines are included for copper and silver, for example, up to eleven for dysprosium. A wave-length scale is lacking, which seems a rather serious omission; if one could have been included in Ångstrom units for the shorter wave-length range and in five Ångstrom units for the higher ranges, it would have been a considerable advantage. The inclusion of a range using glass optics is to be commended for those who have instruments with this additional equipment; hitherto workers in this medium have been rather ignored when aids of this type have been offered.

On general grounds, the spectra suffer from the inherent 'graininess' of the photographic emulsion, a defect that could scarcely be entirely avoided. The wisdom of glossy photographs on thin card for use in a laboratory is questionable, though users can overcome the flimsiness by mounting each card on a thicker backing; a matt finish would probably have been more serviceable.

The price of £26 may seem high, but this is probably justified when one considers the man-hours necessary to make a similar series of charts, even if it be confined to the range more commonly used in any particular laboratory. The ready comparison of the charts in this *Atlas* with spectrograms prepared with Hilger equipment should make it worthy of a place in the spectrographic laboratories where such equipment is to be found, and by no means out of place where other equipment is in use.

J. A. C. MCCLELLAND

π-ELECTRON CHEMISTRY

Molecular Orbital Theory for Organic Chemists

By Prof. Andrew Streitwieser, Jr. Pp. xvi + 489. (New York and London: John Wiley and Sons, Inc., 1961.) 109s.

THIS is a book for which there has long been a need. For although the greatest successes of the theoretical chemists since the advent of the wave equation in 1926 have been in the field of organic chemistry, there has hitherto been no simple account of the whole topic.

Prof. Streitwieser is well qualified to write such an account, for he combines both the experience of the experimental chemist, who knows how hard it is to sort out a genuine measure of the charge around each atom of a molecule, and also the ability of the theoretical chemist, since he has made some notable contributions to our store of calculated quantities. It is this balance between theory and experiment which must count as one of the strongest points in favour of this book. The literature abounds in 'bastard mathematics'—by which I mean poor-quality mathematics which serves practically no purpose because it solves no problems. There is none of that here.

The author has concentrated on π-electron chemistry—which seems for him to be almost synonymous with organic chemistry—and he deals only with the molecular-orbital approximation. This is wise, because by far the greatest successes and the widest applications are within this approximation. He also concentrates almost entirely on the simplest Hückel theory, with no overlap integrals and no allowance for electron exchange (except in the development of the ω-technique, largely developed by the author himself). As a result, the account is excellent for ground states, but becomes much less convincing in those few places where excited states are involved. But it is quite amazing to see what can be done, even with so gross an approximation.

The book is a veritable mine of information and is almost encyclopædic. The author says that in this field, during the 1930-decade, there were published some 20 papers, in the 1940-decade 70 and in the 1950-decade 600. He seems to have included them all. Certainly I could think of scarcely any significant ones that he had left out. Moreover, the applications are multitudinous—to charge distributions, bond orders, polarizabilities, electrode potentials, and particularly chemical reactivity, where he has provided easily the best and most comprehensive account yet published. The text is liberally scattered with excellent diagrams and graphs to show the measure of agreement with experiment.

This is a book which should be accessible to every theoretical organic chemist, and to most experimentalists also. For the story is not too difficult, and the whole pattern of π-electron chemistry is changed because of the work here described. There will be those who shudder occasionally at what will seem hard treatment for their beloved English language ("the hydrogen molecule cannot be solved exactly", "this function peaks at the nuclei", "The reader will recall from his algebra days"). But there seem to be very few actual mistakes, despite the inevitable over-simplifications. If there are still any organic chemists who wonder what good has come out of wave mechanics let them read this volume, they will do well if they avoid being converted by the range of the ground covered, and the author's enthusiasm as a guide. C. A. COULSON

THE MIOCENE TRANSGRESSION

Fundamentals of Mid-Tertiary Stratigraphical Correlation

By Dr. F. E. Eames, Dr. F. T. Banner, Dr. W. H. Blow and Dr. W. J. Clarke. With a contribution by Dr. L. R. Cox. Pp. viii + 163 + 17 plates. (Cambridge: At the University Press, 1962.) 50s. net; 9.50 dollars.

THE correlation of the Mid-Tertiary marine sediments has frequently been based on uncritical, even dogmatic statements in the past, so that some peculiar conclusions have been reached, notably those relating to the fauna ascribed to the Oligocene in America. The authors of the present work have briefly made known in the past decade some of their reasons for rejecting some of the old correlations. Using their wide knowledge of the stratigraphical palæontology of both the Old and New Worlds, they now give their correlation of the Mid-Tertiary marine successions throughout the world, and produce their arguments for lowering the base of the Miocene to include much formerly referred to the Oligocene. They lay considerable emphasis on the Foraminifera, both the larger forms and the assemblages of planktonic forms, especially the Globigerinaceae, but (a basic principle) they also take into account the evidence of the other phyla. The authors point out that assessments so made are liable to error if certain factors are disregarded, such as the influence of facies on the local ranges of a species in different localities, the changed time-values of some fossils owing to modern, more refined evaluation of their characters, and the recognition of widespread disconformities and unconformities. The last, in particular, have sometimes been overlooked in the past, so that re-worked Eocene fossils, often beautifully preserved and incorporated into post-Eocene sediments, have led to false conclusions, especially in America.

Another fundamental principle of the authors is that "the type region for a stage or series of stages must be regarded as constituting the fundamental basic standard". Any discussion of the Miocene in its relation to the Oligocene should, therefore, be based on a clear understanding of the faunas of the European Oligocene and Aquitanian, and the contribution of Dr. L. R. Cox in Part 1 on their marine molluscan faunas is thus of much importance.

Part 1 consists of a review of the criteria for correlating the Mid-Tertiary deposits and a critical revision of the correlations made. The Aquitanian is taken as the base of the Miocene, and naturally much of the evidence for the authors' conclusions concerns the recognition of the Lower Miocene (Aquitanian and Burdigalian) and its relationship to the Oligocene. As their revision moves on from Europe, through the Tethyan area, to Indonesia and beyond, the authors argue cogently for several new interpretations, for example, in Indonesia. It is in the Central American area, however, where they make their most profound changes, lowering the base of the marine Miocene everywhere in the United States, Caribbean region and northern South America, to include nearly all that was formerly designated as Oligocene. The Antigua Limestone is of key importance, for in addition to a fauna of *Lepidocyclina* species of Lower Miocene age, it yields corals (and other macrofossils) which enable correlations to be effected with other Central American areas. Thus the coral-bearing formations previously referred to the Oligocene are shown to be Miocene. The biggest changes affect the Vicksburgian, which had come to be regarded as typical of the American Oligocene, but which the authors argue belongs to the Miocene, and the successions in Venezuela and Trinidad, where anomalies can be explained by the re-working and derivation of Eocene fossils.

Part 2 deals with the Globigerinaceae. A series of biozones, based on the planktonic Foraminifera, and founded on the succession in Tanganyika and on a revision of the species occurring there, is proposed for the Upper Eocene, Oligocene and Lower Aquitanian. The distribution of the assemblages so recognized confirms the results reached in Part 1, and particularly the absence of the Upper Bartonian and the whole of the Oligocene from the Central American region.

A reconsideration of Mid-Tertiary palæogeography follows from the establishment of such a major unconformity (or disconformity), and the authors suggest that, while the Oligocene orogeny was occurring in the archipelagic Caribbean area, "the whole of the southern portion of the United States was uplifted *without* orogeny as a gigantic coastal plain". The widespread Aquitanian transgression that succeeded was in accord with the geological history of the rest of the American region and of the Tethys as a whole.

The arguments put forward by the authors are so logical and well thought out that they carry conviction, and it seems that, in general, only slight adjustments will be necessary to the stratigraphical conclusions at which they arrive. Their correlation-tables are clear and easy to interpret, and the text-figures and plates are excellent. The whole volume is well produced and typographical errors are very few.

H. DIGHTON THOMAS

Annual Review of Microbiology

Vol 15 Edited by Charles E Clifton, in association with Sidney Raffel and Mortimer P. Starr Pp viii+349 (Palo Alto, Calif Annual Reviews, Inc , 1961) 7 dollars

THE fifteenth *Annual Review of Microbiology* provides concise surveys of literature covering a wide range of topics, in this respect it lives up to the standard set by its predecessors The volume contains thirteen reviews, cites more than two thousand references and includes a cumulative index of authors and chapters for Volumes 11–15

Microbiological literature has, during the past decade, become liberally sprinkled with jargon Most microbiologists are now familiar with the terms 'chemostat' and 'bactogen', but 'auxanometer' and 'symbiocon' may leave many puzzled The principles of these and other devices now used for the continuous culture of micro-organisms are admirably presented by James

Studies of microbial metabolism continue to reveal new synthetic capabilities in micro-organisms the biosynthesis of C_2, C_3 and C_4 compounds from C_1 units is discussed in a comprehensive review by Quale All who study microbial metabolism will, ultimately, be faced with problems of cell permeability and membrane transport Cirillo points out that, until recently, it has been common practice either to ignore these problems or eliminate them by the mechanical disruption of cells This is no longer the case Much has been learnt in recent years about active transport mechanisms and 'permeases', these studies have been well summarized by Cirillo in an article entitled "Sugar Transport in Micro-organisms"

Two articles in the present volume will be of the greatest interest to virologists Questions of virus structure are discussed by Colter and Ellem, Zhdanov reviews recent experience with anti-viral vaccines This latter contribution contains some interesting information about the relative merits of different poliomyelitis vaccines

Other topics reviewed include physiology of actinomycetes, fine structure of protozoa, interactions between pesticides and soil micro-organisms, the family Brucellaceae in veterinary research, phage-host relationships in some genera of medical significance, plant-nematode inter-relationships, gaseous sterilization and antigenic variation in unicellular micro-organisms B A Newton

The Ovary

Vol 1 Pp xiii+619 157*s* 6*d* Vol 2 Pp xiii+600 157*s* Edited by Sir Solly Zuckerman Assisted by Anita M Mandl and Peter Eckstein (New York Academic Press, Inc , London Academic Press Inc (London), Ltd , 1962)

THIS magnificent treatise will certainly long remain a standard reference work for the literature on the morphology and function of the ovary

Volume 1 consists of eleven chapters and covers the development and structure of the ovary, including its histochemistry, the ovarian cycle, ovarian pituitary relationship, the mechanism of ovulation, ovarian physiology in the non-pregnant and pregnant female, the menopause, and derangements in ovarian function

The twenty-three chapters of Volume 2 deal with such varied problems as the chemistry and biochemistry of ovarian hormones, the experimental embryology of the ovary, the actions of ovarian hormones on the body, the influence of nutrition and external factors on the ovary, relationship between ovarian hormone secretion and behaviour, transplantation of the ovary, and the relationship between tumorogenesis and the ovary

Each chapter is written by specialists, well recognized in their respective fields, and, thanks to the excellent editorial work of Sir Solly Zuckerman, the whole treatise has a character of harmonious unity despite the multiplicity of necessarily overlapping subjects

It would be impossible to review each chapter of an extensive treatise of this kind in detail, but there can be no doubt about the value of these two volumes not only to endocrinologists but also to comparative anatomists, zoologists and experimental embryologists The treatise is illustrated by numerous photographs, graphs, and tables, its usefulness is greatly enhanced by carefully prepared author- and subject-indexes Hans Selye

Science and World Affairs

History of the Pugwash Conferences By Prof J Rotblat Pp 92+4 plates (London. Dawsons of Pall Mall, 1962) 8*s*. 6*d* paper bound, 14*s* cloth bound

THE most recent Pugwash Conferences have met in the United Kingdom the first at Cambridge on August 25 was attended by 60 specialists on disarmament and arms control, the second in London on September 3, when some 200 scientists from many nations sought solutions to some of the problems created or made tractable by the modern growth of science Prof. Rotblat's readable account of the origin and development of these Conferences on science and world affairs as an important and effective channel of communication between scientists for the study and discussion of the most complex problems now facing mankind thus appears at a most opportune moment

It gives a concise, purely factual account of the first eight conferences, and although Prof Rotblat does not attempt to discuss in general terms the organization of international discussion among scientists, its effectiveness, or the relation of such discussion to Government action, he provides all the material required for an independent and impartial assessment of what has already been achieved by these conferences. He appends to his account the original Russell–Einstein manifesto of December 1954 from which the movement may be said to have stemmed and the several statements issued by the successive Conferences, including the Vienna Declaration of 1958, and the detailed proposals for international co-operation in science which form the substance of the statement from the seventh Conference last September, and there are lists of the participants in all these Conferences He is content to let the facts speak for themselves, and the success which the movement has already achieved is manifestly such as makes the book one which has strong claims on the attention of scientists generally

Prof Rotblat has earned the gratitude of all scientists who believe that science has in its power to make a serious and constructive contribution to world peace and order His book should make a definite contribution to the understanding of what the two Conferences in the United Kingdom represent and their implications for human welfare and scientific advancement R Brightman

THE CHALLENGE OF SPACE RESEARCH

By Sir BERNARD LOVELL, O.B.E., F.R.S.*

Director of the Nuffield Radio Astronomy Laboratories, Jodrell Bank, and
Professor of Radioastronomy in the University of Manchester

OUR present knowledge of the universe is largely based on the work of the optical telescopes, particularly of the 100-in. on Mount Wilson and the 200-in. on Mount Palomar. More recently the radio telescopes have achieved great successes in astronomical research. It is important to appreciate the scale of cosmic distances with which these telescopes are concerned so that we can understand the limitations of the experiments which it is possible to do in space probes.

About 25 years ago, we believed that all the stars of the universe were concentrated in the Milky Way system which we see with the naked eye in the sky at night. We believed that the totality of the cosmos was represented by an almost spherical enclosure with the Sun and its planets conveniently situated in the centre of the system. But observations made with the Mount Wilson telescope just after the First World War showed that the real situation was quite different. Now we know that the Milky Way is an assembly of about 100,000 million stars arranged in a flattened disk so large that a ray of light, travelling at 186,000 miles per second, would take 100,000 years to traverse the system. Moreover, the Sun, instead of being situated in the centre of this stellar system, is in a very unprivileged position right out in one of the spiral arms of the galaxy. The distance of the Sun from the nucleus of the galaxy is about 30,000 light years, and we are so unfortunately situated that with the optical telescopes it is not possible to study these central regions because of the obscuration by the dust which exists between the stars. This entire system is rotating like a cartwheel and the stars on the perimeter take about 200 million years for a whole rotation. It was soon realized that this enormous assemblage was only a very small part of the cosmos. Herschel speculated that the nebulosities which could be seen in the Milky Way might be systems of stars far removed from it. This remained a speculation until Hubble succeeded in measuring the distances of some of the stars in these nebulosities. Then it was appreciated that we were dealing with other entire galaxies of stars situated so far away from our own Milky Way system that the light from the nearest of them in Andromeda was taking about 2 million years on its journey towards us. This great spiral galaxy in Andromeda is the only extragalactic nebula which can be seen with the naked eye. We know now that there are vast numbers of similar galaxies in the universe each of which contains, perhaps 10,000 or 100,000 million stars.

The large telescopes reveal the existence of these galaxies of stars out to distances such that the light takes thousands of millions of years on its journey through space. The 200-in. telescope on Mount Palomar, a few years after it came into operation, succeeded in photographing a cluster of galaxies in Hydra the distance of which was determined as 2,000 million light years. More recently, with the co-operation of the radio telescopes, the range of identification has been increased to something like 5,000 million light years. Within this region of time and space there must be thousands of millions and probably trillions of these galaxies which appear to be distributed uniformly, at least on the large scale.

One of the most remarkable features of these observations is that the galaxies are receding from one another at high speed. At the limit of our present penetration the speed of recession is about 46 per cent the velocity of light, that is about 86,000 miles a second. These distances are quite vast compared with the kind of distances with which we are concerned on Earth. An imaginary journey at the speed of light, 186,000 miles a second, would enable us to encircle the Earth 7 times in the first sec, after $1\frac{1}{2}$ sec we could pass the Moon, in 8 min we would pass the Sun, and in about $6\frac{1}{2}$ h we would be removed entirely from the Solar System. After $4\frac{1}{2}$ years we would reach the nearest star, after about 50 or 100 thousand years we would pass out of our own Milky Way system, after 2 million years we would reach the nearest nebula in Andromeda and so we could go on for many thousands of millions of years traversing the regions of time and space which are accessible to our present-day instruments.

These results with the big telescopes have been obtained because man has the ability to look out into space through rather a small transparency or gap which exists in the Earth's atmosphere. This extends over the colours of the rainbow, and it is through that region of the spectrum that it is possible to get a clear view of the heavens. If human beings had evolved with eyes which were sensitive in a slightly different part of the spectrum towards the infra-red or ultra-violet we would have had very little knowledge of outer space. This restriction of man's view of the universe was not thought to be of any great consequence because it was known that a hot body, like a star or the Sun, generates most of its energy in the visible part of the electromagnetic spectrum. Even after Jansky discovered that radio waves were incident on the Earth, in the radio part of the spectrum, astronomers were not particularly excited about it. Now we realize that this other transparency in the atmosphere is extremely important, because the radio telescope which picks up the radio waves from space has enabled us to penetrate very far indeed into the depths of space. Indeed, it seems likely at the present time that the big radio telescopes are penetrating much farther than the known 5,000 million light years limit of the most distant identified cluster of galaxies, and probably so far as man ever will be able to penetrate into space. We believe that this new-found ability to investigate the remote epochs of space and time is of great consequence to the problem of the origin of the universe, but the present occasion is not appropriate for further discussion of this exciting work.

---

* Substance of an address delivered before the Institute of Strategic Studies at Brighton on May 14.

Scientific Significance of the Earth Satellite and Space Probe

Our earthbound instruments look out into space through the transparencies in the optical and radio parts of the spectrum where there is no significant absorption in the atmosphere or ionosphere It was realized that there were a number of problems awaiting solution when it became possible to fly scientific instruments outside the atmosphere and ionosphere but it was not anticipated that our ability to launch instruments in space probes or Earth satellites would give us entirely unexpected results about the conditions in the Solar System or in the universe In the event, the early experiments with scientific instruments in the Earth satellites produced some remarkable results

For the scientist the importance of these space activities is the ability to get instruments outside the obscuring and absorbing layers of the Earth's atmosphere in order to investigate those parts of the spectrum which are wholly or partially obscured from instruments on the Earth It is important to emphasize this point because on the cosmic scale the possible penetration of these vehicles into space is minute Indeed, so far as it is reasonable to look ahead, the useful penetration of the space-vehicles will be confined to the nearer parts of the Solar System The Earth is 93 million miles distant from the Sun or 8 light min The orbits of the inner planets Mercury and Venus lie between the Earth's orbit and the Sun At closest approach Venus is about 25 million miles from Earth, and Mercury about 50 million miles The orbit of Mars lies outside that of the Earth and at closest approach its distance from the Earth is about 34 million miles These distances of a few tens of millions of miles represents the immediate ambition of space technologists so far as the possibility of getting scientific instruments into space is concerned It seems unlikely that in the foreseeable future there will be much hope of placing scientific instruments into the region of space of the outer planets Jupiter, Saturn, Uranus, Neptune and Pluto In the case of Jupiter a journey of about 368 million miles would be involved and ten times that distance for the outermost planet Pluto

If success is ultimately achieved in sending space-vehicles to the extremes of the Solar System the distances involved so far as penetration into cosmic space is concerned are insignificant Even with the outer planet of the Solar System, Pluto, we are concerned with a planet which is only a few thousand million miles distant from Earth, whereas the nearest star is 20 million million miles away The light from the Sun takes 6½ h on its journey to the orbit of Pluto, but 4½ years to the nearest star Thus, for any space experiments in which proximity of instruments to the object of investigation is concerned, only the inner reaches of the Solar System are at present open to study and in decades to come perhaps the region of Jupiter and the nearer of the outer planets

Scientific Dividends of Space Research

Until 1958 we believed that the immediate environment of the Earth was defined by the zones of electrified regions, known as the ionosphere, extending to 400 km or so above the Earth There seemed no reason to doubt that the upper part of this ionosphere represented the extent of the Earth's geophysical control It was a reasonable assumption that if scientific instruments were despatched to a height of more than 500 km above the surface of the Earth they would be in a truly interplanetary environment, and would be influenced only by the particles and radiation under the influence of the Sun, largely unaffected by the presence of the Earth

It is probably correct to say that most of the original concepts for work with Earth satellites were concerned either with information about the Earth itself or with the more detailed studies of the pressure, temperature and depth of the atmosphere, and with a fuller understanding of the incident radiations which controlled the ionosphere and atmosphere In actual fact the discovery made by Prof J A Van Allen in the first American satellite, *Explorer I*, demonstrated that this concept of the environment of the Earth was far too restricted *Explorer I* carried instruments which were specifically designed to study the radiation impinging on the atmosphere from the Sun and outer space The instruments ceased to function because they became blocked with intense radiation in certain parts of the satellite orbit Van Allen had discovered that the Earth is surrounded by radiation belts in which fundamental particles—mostly protons and electrons—are trapped in the Earth's magnetic field

These radiation zones are now known to extend from about 4,000 miles above the Earth to 50,000 miles, where there is a gradual merging into the interplanetary environment At the moment there is uncertainty about the precise arrangement and origin of the particles in these zones For some time after the initial discovery it was believed that there were two main zones of trapped particles, the one nearer the Earth consisting of protons, and an outer zone consisting of electrons However, it seems from the recent analysis of the American results that it may be wrong to think of these zones as two separate entities, and that they may be manifestations of a continuum of trapped particles extending out to 50,000 miles from the Earth

The origin of these particles is a question of dispute It is believed that the protons in the inner zone may be the result of processes which have taken place in the atmosphere of the Earth There, neutrons are produced by cosmic ray bombardment The neutrons decay into protons and electrons as they move out into space and the protons are trapped in the magnetic field The trapped particles spiral around the Earth's field making the journey between the two hemispheres in a second They are reflected at the mirror points and continue in this trapped condition with the whole shell moving around the Earth once a day The origin of the electrons in the outer zone is also uncertain One significant observational fact is that the density of the trapped electrons is very closely under solar control in the sense that when there are magnetic storms or solar eruptions the particles tend to drain from the zone and it takes some time for it to be repopulated This suggests that this zone is composed of particles which are actually streaming from the Sun—the solar wind This interpretation is not altogether satisfactory because it is not certain how such particles could actually be injected into these orbits around the Earth

The further details of this new work need not concern us here, but for our present purpose it is important to remember that in the few years since Van Allen made his first observations in *Explorer I* our entire conception of the immediate environment of the Earth has been transformed in a way which no one could have anticipated. It is true that many years ago the Norwegian astrophysicist Stormer described how particles could be trapped in the Earth's magnetic field in this way, but his theory concerned the formation of auroræ and I do not think that any scientist really anticipated that the Earth was permanently enclosed in such a shell of particles In 1957 we believed that we would move into outer space a few hundred miles above the Earth's surface Now we know that we would have to travel to distances of about 50,000 miles above the Earth's surface before we would find ourselves in a truly interplanetary environment

These new results are well correlated with the development of our general concepts about the solar system For a long time the Earth and the planets have been regarded as bodies under the gravitational control of the Sun but otherwise physically isolated Now it appears that the whole system is much more of a unity and that we must regard ourselves as being enveloped in the very tenuous corona of the Sun itself It seems probable, both from this work with the space probes and from some recent experiments with the radio telescopes, that we are, indeed, enveloped in the corona of the Sun and closely under the control of the solar forces This probably applies also to the other planets in the Solar System Here we have one example demonstrating in a remarkable manner the unexpected dividends which have come from the investments in space research

A subject which has been reserved for experiments in Earth satellites and space probes is the problem of the dust which exists in the Solar System These dust particles are manifested on Earth as shooting stars in the atmosphere, and occasionally by meteorites which plunge to Earth These particles move under the gravitational attraction of the Sun, and are often associated with comets Contrary to older beliefs we are now certain that these meteoric particles are confined to the Solar System and are not transient visitors from interstellar space Occasionally, the Earth in its journey around the Sun passes through a particular concentration of débris which may itself be in a cometary orbit Then we see a display of shooting stars which may last for several nights until the Earth emerges from the débris The Earth sweeps up vast quantities of material in this way. With the unaided eye it is possible to see meteors down to about the 5th or 6th magnitude in a clear dark sky Down to this limit there are something like a hundred million of these particles burning up in the atmosphere of the Earth every day

The techniques of radio astronomy have greatly facilitated and extended these observations, and we now have observational data which take us down to the extremely small infra-visual particles Something like 10,000 million of these particles bombard the Earth's atmosphere every day, and the smallest of them which give a detectable trail observable with a radio telescope weighs only a ten-thousandth of a gram Particles of even smaller size exist in much greater quantities but these are so small that they are stopped by the atmosphere before they burn up, and they descend slowly to Earth as small particles of dust known as micrometeorites Our knowledge of the existence of these actually came from the inspection of the sediments at the bottom of the ocean The investigation of these micrometeorites in space as solid bodies could only be made by instruments in satellites moving outside the Earth's atmosphere In the past few years our knowledge of these particles has been greatly increased, since many of the satellites and space probes have measured the impact of dust grains weighing only a thousand-millionth of a gram It is believed that the Earth possibly collects something of the order of a few million tons of this material every year

As a third and last illustration of the discoveries which have already been made in space-vehicles we refer to another unexpected result This work concerned the investigation of cosmic rays and was carried out by Prof J A Simpson of Chicago in the space probe *Pioneer V* It has been known for a long time that the recordings on Earth of the cosmic rays which originate somewhere in the universe were effected by magnetic disturbances When the Earth's magnetic field is disturbed, for example on the occasion of a solar flare, there is a decrease in the intensity of the cosmic rays recorded on Earth It had been commonly assumed that the effect was local and that it was the change in the Earth's magnetic field which was altering this influx of cosmic ray particles When the space probe *Pioneer V* was about 10,000 km from the Earth there was a magnetic storm and Simpson's apparatus in the probe recorded a decrease in the cosmic ray intensity simultaneously with the decrease observed on Earth This straightforward observation is of great importance, since it demonstrates without ambiguity that the original interpretation that these decreases are confined locally to the Earth was erroneous Clearly we are dealing with a modulation of the cosmic ray particles from space in the Solar System itself Apart from the importance of Simpson's observations to our understanding of the cosmic ray phenomena the experiment has significant repercussions on our beliefs about the magnetic fields in the Solar System The effect demonstrates that there are variable magnetic fields in the interplanetary space, presumably carried by the plasmas ejected from the Sun during the upheavals caused by the solar flares

Tasks for the Future

These experiments which have been made in space so far are merely a beginning to the work which scientists hope and expect to carry out with the space probes of the future From the astronomer's point of view it seems possible that the future space probes can make great contributions to our understanding of the origin of the Solar System I think that this question of the origin and evolution of the Solar System, coupled with the study of the problem of the existence of organisms elsewhere in the Solar System, are issues which will become vital when space probes with working instruments can land on the Moon and reach the vicinity of Mars and Venus I would assess this general problem as the most significant task to which space science should adapt itself on a large scale

The problem of the evolution of the Solar System is one of extreme difficulty, and I sometimes think that it is even more difficult than the problem of the evolution of the cosmos itself After all, if one is concerned with the study of how the universe came into existence, then our modern radio telescopes penetrate so far into the cosmos that it is now possible to study the conditions in the universe as they existed more than 5,000 million years ago It is not possible to study the past history of the Solar System in this way Our knowledge of the Solar System is effectively of time present and we have no possibility of observing similar events happening elsewhere at the present time Therefore we must try to devise some observational test of a multitude of theories as to how the Earth and the planets came into existence.

The old idea was that the primeval material of the Earth and the planets was torn out of the Sun by a passing star and that this material afterwards cooled down and formed the Solar System as we know it to-day. This theory had two important consequences. One was that the process which gave rise to the birth of the Solar System must have been an extremely rare one, because, although there are such a great number of stars in the Milky Way system, a close approach of two stars in this way is an unlikely event. The second corollary was that the Earth was formed in a hot state and therefore the evolution of any life forms on it must have been a subsequent event after it had cooled down.

Our present knowledge leads to the belief that such a sequence of events is quite out of the question. Although many details remain to be completed it seems probable that the planets and the Earth came into existence by quite a different process. About 5 thousand million years ago the Sun was surrounded by a nebula of gas and dust. The Sun attained this nebula either in the process of its birth in a great star cloud, or it collected the nebula as it passed through one of the dust clouds in the Milky Way system. During the course of the next few thousand million years this nebula of gas and dust aggregated into successively larger bodies which eventually formed the Earth and the planets as we see them today. The evidence for this comes from the assessment of the relative abundances of the different kinds of elements in the solar atmosphere, in the meteorites, which are probably bodies of lunar size which were formed in the beginning and then broke up in collisions and from the studies of the abundances of the elements in the planetary atmospheres and on Earth. Analysis of the meteorites indicates that they lost their uranium about 4½ thousand million years ago, and this would appear to be the last occasion on which any really violent processes took place during the evolution of the Solar System.

In order to fill in the details of this problem it is important to obtain access to material which lies in the Solar System other than that which is brought to us occasionally by the meteorites which come to Earth, because the trouble there is that we do not really know how the meteorites themselves originated. This I think is the most significant part of the lunar space programmes now in preparation—namely the possibility of studying the details of the composition of the lunar dust and the lunar substrate in order to assess the relative abundances of the elements, compared with those which we have on Earth, on meteorites, and those which we find in the solar atmosphere.

The second problem concerns exobiology. That is the great issue as to whether life as we know it is unique. On the old theory of the origin of the Solar System it seemed inevitable that life was unique because the processes of formation of the Solar System appeared to be unique. Now the position has changed and the discovery of the probable existence of organisms elsewhere in the universe is important. As an astronomer I do not think there is an astronomical problem remaining, because the processes which we believe led to the formation of the Solar System must have been of frequent occurrence in the universe. It is not difficult to estimate how many stars in the universe are likely to have planetary systems. Even on the most pessimistic assumption this comes to about 5 per cent of the stars in the galaxy and in all the extragalactic nebulæ. How many of these stars with planetary systems have at least one planet which is in a sufficiently stable condition for a few thousand million years to support long-term evolution? The answer is that about half of one per cent of the stars in the cosmos have planets of which at least one member may be in a sufficiently stable condition to support long-term evolution. This means that there are vast numbers of possible abodes of life in the universe. In the Milky Way alone the one-half per cent means a thousand million. Then in the entire cosmos there must be many trillions of possible abodes for organic evolution.

The question is, therefore, not astronomical, but biological. This is where the future space probes could make their greatest impact on man's knowledge of the universe with the utmost repercussions on our life and thought. The question which the space probe has the possibility of answering is whether the primeval organisms exist elsewhere in the Solar System. This evidence must be carried by the planets Mars and Venus, and there is reason for believing from the recent discoveries of Calvin and Vaughn and of Prof. Nagy and others of life-forms in the meteorites that the answer will be in the affirmative [*Nature*, **193**, 1119, 1962]. Therefore, I would class the investigation of the lunar structure, from the point of view of the evolution of the Solar System, and the exobiological investigations of the atmospheres and surfaces of Mars and Venus, as the great and unique tasks of space science in the future.

A grave warning must be given, however. In the various excitements of carrying out these probings neither of the great nations who are engaged on this and have the only opportunity of carrying it out at the moment—the U.S.S.R. and the U.S.A.—must ruin our chances of making the discoveries because of national anxiety to be first. It is quite clear that the ejection of a rocket such as *Lunik II* on to the surface of Mars and Venus would be a very great scientific and moral disaster because by its contamination it would prejudice for ever the possibility of reaching a valid conclusion about the existence of organisms developing elsewhere. It is absolutely essential that these biological investigations be carried out carefully in a considered way with an assessment of the situation by probes moving remotely from the planets before actual impacts are attempted.

Value of the Investment

It is against this background of the present and future scientific activities in space that one must inquire if the investment is worthwhile. May I say straight away that I am a great believer in space research; but I have been asked to attempt to separate the worthwhileness of the investments in space for purely scientific research from all the other associated activities particularly the military, industrial and commercial enterprises such as, for example, communications, weather forecasting and navigation. Even with all these associated benefits removed my answer is a simple one, that no community can continue to thrive unless it invests in space research to the utmost. On the other hand this must be accompanied by a warning. In an extreme case, suppose a decision was reached that Great Britain had to engage in these activities, then her entire scientific budget of about £400 million would be only sufficient to make a start with the kind of space activities which are now being carried out by the National Aeronautics and Space Administration of the United States. Therefore to do that, that is to shift all the science of Britain on to these space activities, would be nonsensical, because the quantitative yield of results per investment per million pounds per thousand scientists in the space programmes is rather small compared with the results which can be obtained with the same kind of investment in earthbound instruments, such as optical telescopes and radio telescopes. Hence, although the case for investment to the utmost in space research is so strong it must be done at the sacrifice of something other than a country's current scientific budget. It is useless to attempt to fit these new activities into an existing scientific budget. There must be a new outlook and a new budget on the biggest possible scale. Unfortunately in Great Britain we have not realized this. In the United States the situation has been realized admirably and in time, because it is evident that the battle between East and West is seen by the U.S.S.R. as a conflict in the field of science and technology. This issue has been joined by the Americans, but in Great Britain there is little appreciation of the fundamental issues at stake.

May I conclude by saying that in spite of this enthusiasm which I display and this optimism for the future of scientific research I must confess that my belief in the inevitability of progress has been very considerably undermined during this past year by the realization that some of the American and probably some of the Russian space activities are not being guided by the purest of scientific motives. I refer of course to the military programme by the U.S. Air Force for the orbiting of 'Project Needles (West Ford)' around the Earth and more recently the proposed explosion of a megaton nuclear weapon in the region of the Van Allen belts [see following article]. These subjects are unusually controversial, and the only point I would make now is to emphasize the extreme importance of carrying out such projects only by agreement of the International Scientific Unions. If I might end on this rather sad note I do beg the Americans to use their influence to the utmost to make quite sure that such projects are carried out only by international agreement and particularly within the framework of the resolution of the International Astronomical Union which was phrased only a few months ago in California. If this is not done then the United States may bear the awful responsibility of having started a chain of events leading to the militarization of space and the destruction of astronomy on Earth. [See leading article in *Nature* of August 25, p. 739.]

Note added in proof by the author. This address was delivered to the Institute of Strategic Studies nearly four months ago. In this time there have been further space activities which underline the anxiety expressed in the last paragraph of my address [see also p. 945 of this issue]. The United States exploded the megaton bomb outside the atmosphere and have thereby enormously confused the study of the natural radiation belts by setting up a new long-duration zone of trapped particles. A few more explosions of this type for military purposes by either of the Powers will obviously add so much artificially trapped material to the radiation zones that the investigation of the natural effects will have to be abandoned before we know their true nature or origin. The U.S.S.R. have launched *Vostok* 4 into an orbit so accurately controlled that it came within a few miles of *Vostok* 3 launched 24 h earlier, and recovered both space ships on Earth within 6 min of each other in the assigned landing zone. Whether or not this exploit had military backing, it demonstrates further the military potential of space in terms of rendezvous, and orbital bombs. Finally, a highly successful communication satellite, *Telstar*, has been placed in orbit and thereby encouraged the commercial as well as the military communication interests in space. The anxiety expressed about 'Project Needles' must be paralleled by the anticipation that many *Telstar* or *Echo* balloon satellites will have a similar detrimental effect on earthbound astronomy and radioastronomy. The need for international agreement about the use of space and the control of launchings, either of rockets or space-vehicles into it, has become a matter of the utmost urgency.

GEOMAGNETICALLY TRAPPED RADIATION PRODUCED BY A HIGH-ALTITUDE NUCLEAR EXPLOSION ON JULY 9, 1962

By Dr. B. J. O'BRIEN, Dr. C. D. LAUGHLIN and Prof. J. A. VAN ALLEN
Department of Physics and Astronomy, State University of Iowa, Iowa City

THIS is a preliminary report of investigations made with the satellite *Injun I* of the artificial radiation belt produced by a nuclear device recently exploded at a high altitude. The officially available information on this burst is contained in the international *AGIWARN* message of July 9, 1962, "... a megaton yield range device was detonated in the ionosphere at an altitude of hundreds of kilometers in the vicinity of Johnston Island in the Pacific at 0900 U.T. on July 9, 1962". The geographic position of Johnston Island is 16.7° N., 190.5° E.

For every kiloton fission explosion in the device, there were produced about 10^{23} fission nuclei the radioactive decay of which yielded some 5×10^{23} electrons[1] having, presumably, a differential number energy spectrum approximated by $3.88 \exp(-0.575 E - 0.055 E^2)$, for the range $1 \lesssim E \lesssim 7$ MeV, where E is the β-ray energy in MeV, and the spectral expression is in units of β-rays per fission per MeV (ref. 2). Some of these electrons were injected at such pitch angles to the geomagnetic field vector that they were temporarily trapped, executing oscillatory motion in latitude along magnetic field lines and drifting eastward in longitude to form an artificial radiation belt encircling the Earth. This is the first reported case of a significant, artificial injection of durably trapped particles into the geomagnetic field since the *Argus* tests of 1958[3,4].

Experimental Details

The present article is based on observations made with the State University of Iowa satellite *Injun I*

(1961 omicron 2) which was designed for study of the naturally occurring radiation belts It was launched at 0423 U T on July 29, 1961, into an orbit with apogee altitude 1,010 km, perigee altitude 890 km, inclination 67° and period 104 min The satellite transmits real-time data from its array of radiation detectors on command from several ground stations, distributed around the world[5]. For the present purposes the telemetry data from the following stations are of significance Quito, Lima, Salisbury (Southern Rhodesia), Iowa City and several Pacific Island stations

There are three particle detectors on *Injun I* the outputs of which are used in this preliminary investigation, but in a more detailed analysis now being undertaken another seven detectors will give useful information

Detector 1 An end-window Geiger tube (Anton type 213) with shielding of 1 2 mg cm^{-2} over a conical field of angular diameter 30°, and 4 5 g cm^{-2} of lead elsewhere (L Frank, private communication)

Detector 2 A similar Geiger tube completely encased in a shield of 3 5 g cm^{-2} of lead and a further 1 g cm^{-2} of stainless steel

Detector 3 A *p-n* junction detector with an electronic bias of 1 MeV and a conical field of view of angular diameter 30° shielded by 2 mg cm^{-2} Shielding elsewhere is $\geqslant 3$ g cm^{-2} (G F Pieper, private communication)

An abridged summary of properties of the detectors is given in Table 1

Table 1 PARTICLES DETECTABLE BY DIRECT PENETRATION

	Electrons	Protons
Detector 1	Energy $E \gtrsim 40$ keV	$E \gtrsim 500$ keV
Detector 2	$E \gtrsim 6$ MeV	$E \gtrsim 45$ MeV
Detector 3	($E \gtrsim 1$ MeV order of 1 per cent efficiency)	$1\ 5 \leqslant E \leqslant 15$ MeV

It is tentatively estimated that the response of *Detector* 2 to the fission electron spectrum is due dominantly to direct penetrations of the shield by energetic electrons ($E \gtrsim 6$ MeV) and not to the bremsstrahlung of the more abundant non-penetrating ones This estimate is being re-examined by further laboratory examination The following investigations of the spatial extent and the time-decay of the artificial radiation zone are essentially independent of the validity of the foregoing working hypothesis

Detectors 1 and 3 are directional, and their response depends on the angle at which they point with respect to the magnetic field vector Both have associated background detectors which measure any penetrating contaminating radiation *Detector* 2 is an omnidirectional detector and provides the simplest means of mapping out the natural and artificial radiation zones, since its response is independent of the orientation of the satellite

A fuller description of the *Injun I* system is given in the previously cited paper of O'Brien *et al* [5]

Some General Considerations on Geomagnetic Trapping

The dynamics of geomagnetically trapped particles as recently reviewed by Van Allen[6] are applicable to the particles injected by the Johnston Island burst In particular, it is necessary to use the fully detailed properties of the real geomagnetic field in order to make a systematic study of spatial distribution and time-decay The co-ordinate system of McIlwain[7] is used here to replace the three geographic co-ordinates longitude, latitude and altitude with the two 'natural' geomagnetic co-ordinates B and L

The value of L is constant for a given line of magnetic force along which a charged particle oscillates in latitude It also labels a unique magnetic shell on which the particle drifts in longitude Numerically, L is such that if the geomagnetic field were that due to a simple dipole, then the equatorial radial distance from the centre of the Earth to a given magnetic shell would be L Earth radii The strength of the magnetic field at a point in space is B gauss

In a time-stationary state, at any two points in space with the same values of B and L the intensity of trapped particles is the same In the equatorial regions at *Injun* altitudes of $\sim 1,000$ km there are trapped the particles of the inner radiation zone which is relatively stable with time During the first year of observations by *Injun I*, some ten million measurements were made in the inner zone Hence the counting-rates of all detectors due to naturally occurring trapped particles are well known and are tabulated in B, L co-ordinates The intensities of the natural inner radiation zone as it was before the burst are used in this article as reference-levels As will be seen in the following, the intensities due to the artificially injected particles are much greater than normal intensities in the inner zone, especially at the lower altitudes This fact must be clearly recognized by those conducting flights in this region during 1962 Furthermore, because of it, we do not treat in this article any possible effects of the burst on the former inner zone particles themselves

The dependence on B and L of particle intensity in the inner zone is shown in Figs 5 and 6 of ref 7 using data from detectors on the satellite *Explorer IV*, which also observed the artificial belts of electrons resulting from the three *Argus* bursts[4] The shielded Geiger tube on *Explorer IV* had shielding significantly less than that of *Detector* 2 above and had an effective area about five times larger than that of *Detector* 2

Before the Johnston Island burst, the counting-rates of *Detectors* 1, 2 and 3 in the equatorial region were dominantly due to inner zone electrons, protons and protons, respectively After the event, there are three possible contributions (*a*) from penetrating electrons from fission decay, (*b*) from decay products of neutrons produced in the explosion, (*c*) from a redistribution in space of naturally occurring trapped particles The observed spectrum in equatorial regions is in crude accordance with the assumption that the dominant contribution is from penetrating fission-decay electrons

As to contribution (*b*), according to Latter, Herbst and Watson[1] about one neutron per fission escapes from a nuclear burst The subsequent neutron-decay injection process yields a more-or-less uniform 'source function' of electrons with $E \lesssim 780$ keV and energetic protons mostly with $E \sim 1$ MeV over an immense region of space By contrast, there is a comparable number of fission-decay electrons, which come from a localized 'source function' and are much more energetic and penetrating In this article we consider only the equatorial regions where the localized 'source function' of fission-decay electrons is large In this region it can be shown that neutron-decay products would have had less effect on *Detectors* 1, 2 and 3 than would the naturally occurring particles of the inner radiation zone

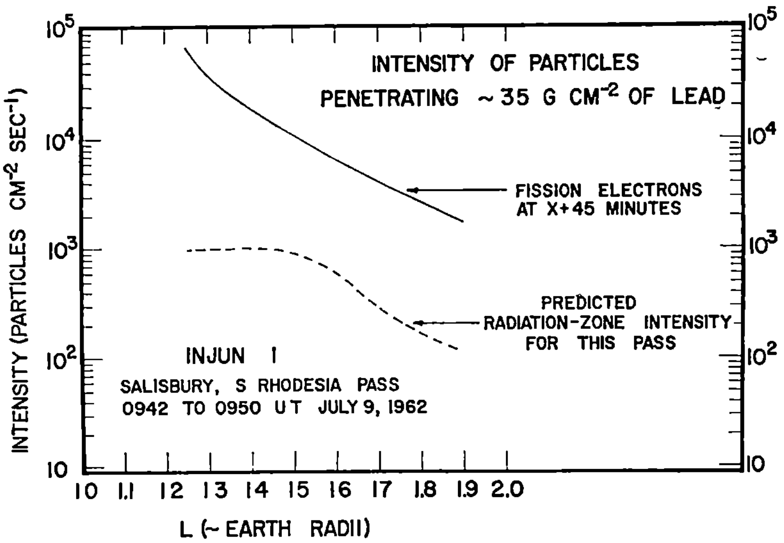

Fig. 1. Comparison of the intensity of the new artificial radiation belt and the natural inner radiation belt measured with *Detector* 2 in the same region over Southern Rhodesia. In calculating the intensity, the assumption is made that the detector is efficiently counting only fission electrons with $E \gtrsim 6$ MeV (see text)

As to contribution (*c*), the pre-burst peak counting-rate of *Detector* 2 at *Injun* altitude was only about 700 counts sec^{-1}, and its extrapolated rate in the heart of the inner zone was only about 1,200 counts sec^{-1}. Yet it reached rates of more than 11,000 counts sec^{-1} after the burst, and it seems clear that such rates could not have resulted from any reasonable redistribution of naturally occurring trapped particles.

Therefore, it is tentatively assumed that the dominant contribution to *Detectors* 1, 2 and 3 in equatorial regions after the burst was from penetrating electrons from fission decay. The validity of this assumption and its applicability at higher latitudes are being further examined.

Early Effects of the Explosion

Injun I was at longitude 224° E., latitude 36° N. and altitude 886 km and was moving north-east at the nominal explosion time of 0900 U.T. on July 9, 1962. We call this time $t = X$ h. *Injun* was not transmitting at the time.

Injun was transmitting over Salisbury, Southern Rhodesia, at $X + 45$ min. Thus it raced the slow electrons eastward around the world, and only electrons with energy $E \gtrsim 500$ keV would have drifted around from the explosion to Salisbury by the time of the pass (Figs. 1.2 and 1.3 of ref. 6 for longitudinal drift period as a function of energy).

Table 2. EARLY MEASUREMENTS OF PARTICLE INTENSITIES (ASSUMING THAT ONLY ELECTRONS ARE PRESENT)

	Detector 1 Intensity electrons $E \geqslant 40$ keV particles (cm^2 sec sterad)$^{-1}$	*Detector* 2 Intensity electrons $E \geqslant 6$ MeV particles (cm^2 sec)$^{-1}$	*Detector* 3 Intensity electrons $E \geqslant 1$ MeV particles (cm^2 sec sterad)$^{-1}$
$X + 45$ min			
(*a*) Normal to $\vec{B}$ at $L = 1.32$	3×10^7	3.5×10^4	$\sim 10^7$ (order of magnitude estimate)
(*b*) Peak intensity at $L = 1.26$	—	6.5×10^4 (see Fig. 1)	—
$X + 100$ min			
(*a*) Normal to $\vec{B}$ at $L = 1.35$	2×10^6	2×10^2	—
(*b*) Peak intensity at $L = 1.13$	—	2.5×10^3	—

By $X + 45$ min there was a shell of trapped electrons extending out to at least $L \sim 1.9$ over South Africa (Fig. 1).

The satellite was also transmitting over Johnston Island at $X + 100$ min and so it arrived there ahead of any electrons with energy $E \lesssim 500$ keV which were drifting around the world, but it would have started to overtake lower-energy electrons after passing Johnston Island.

In these two passes, the directional *Detectors* 1 and 3 were not pointing at right angles to the magnetic field at the times when the omnidirectional *Detector* 2 indicated that the particle intensity was at its maximum. In the intensity measurements listed in Table 2 we quote:

(*a*) Intensities measured by *Detectors* 1 and 3 when they were pointed perpendicular to the magnetic field, that is, when they were measuring the peak directional intensity of particles at that place and time. The intensity measured by the omnidirectional *Detector* 2 at the same place and time is also given. From such data the electron energy spectra may be obtained. Then

(*b*) The peak intensity observed by *Detector* 2 during the same pass is listed. The spectral data of (*a*) may then be normalized to the peak intensity of (*b*) if it be assumed that the electron spectrum is the same at the two locations. This matter is being investigated in detail.

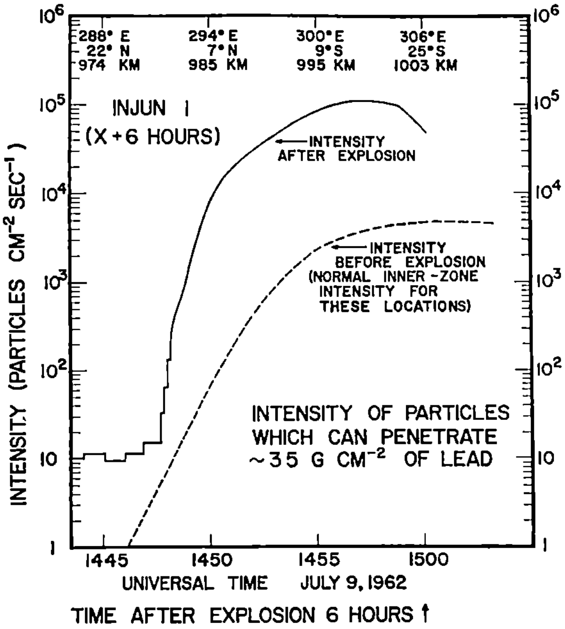

Fig. 2. Comparison of the observed particle intensity after the explosion with the normal zone intensity for a pass over South America. The locations shown are in geographic co-ordinates

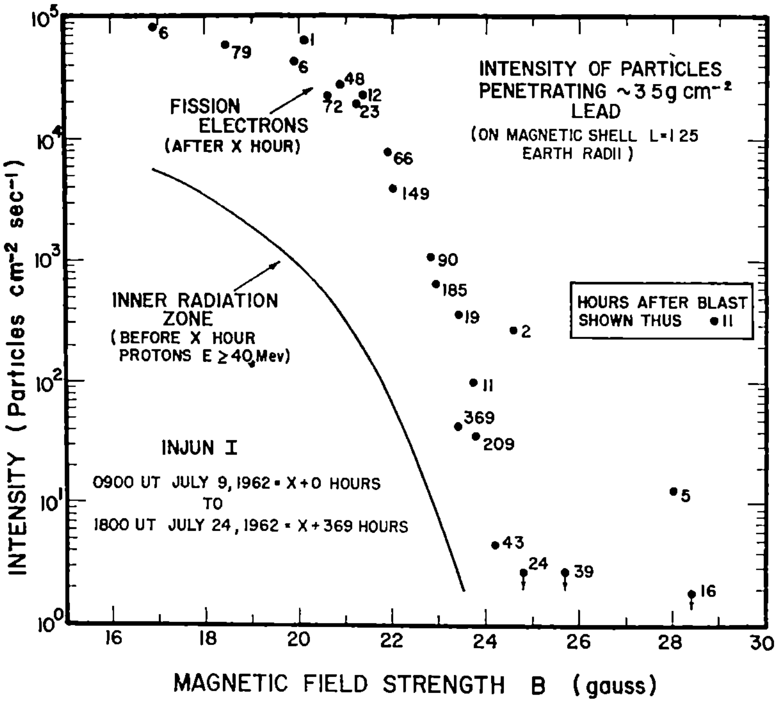

Fig. 3. Variation of particle intensity on the magnetic shell $L = 1·25$ Earth radii as a function of magnetic field strength (B) and the elapsed time since the explosion. The intensity decreases most rapidly at large values of B, that is, at low altitudes. A measurement obtained very recently and not plotted was an intensity of ($4·3 \times 10^4$) particles cm^{-2} sec^{-1} at $B = 0·192$ gauss at ($X + 459$) h. Note that this was after the moderate magnetic storm of July 26

The lower intensity over Johnston Island than over Salisbury is due presumably to the fact that a given geographical altitude over Johnston is equivalent, geomagnetically, to one several hundred kilometres lower over Salisbury. The decay of intensity in both the short term and the long term is dominated by the atmospheric density at the longitude at which the mirror points of particles are deepest in the atmosphere (see later). The dependence of particle intensity at a given value of L and at low altitudes is an extremely strong function of B for both the natural and artificial radiation zones for $L \lesssim 1·5$. For example, in the normal inner radiation zone the particle intensity changes by an order of magnitude over an altitude change of less than 100 km.

In Fig. 1, the enhancement after the explosion of the intensity of particles which could penetrate more than 3·5 g cm^{-2} of lead is clearly shown for Salisbury at $X + 45$ min. The enhancement is about one hundred-fold around $L \sim 1·2$. Over Johnston Island the enhancement near the peak of the artificial zone around $L \sim 1·13$ was more than one thousand-fold.

From data such as those shown in Figs. 1, 2, 3 and 4, it is estimated that there were of the order of 10^{24} freshly injected and trapped electrons of energy $E \geq 1,500$ keV in the geomagnetic field at $X + 1$ h. The total mass of these particles which have created this intense radiation belt is therefore only of order 1 mg.

Long-Term Observations

There is considerable interest in a detailed observational study of the time decay of the artificial radiation belt over a period spanning both magnetically quiet and magnetically disturbed conditions. Such a study is in progress. The moderate magnetic storm of July 26, 1962, did not have any pronounced effect, but further studies with other storms must be made. The results may be expected to be of value in determining the loss-rates of naturally injected particles and hence the source strength for such particles. Hopefully, some of the uncertainty concerning the origin of the inner zone can be dispelled.

In this preliminary report, the rate of loss of electrons of $E \gtrsim 6$ MeV only is considered, and this briefly. Data from a single pass are shown in Fig. 2. From many such passes, the particle intensity on a given magnetic shell, say $L = 1·25$ as in Fig. 3, is plotted as a function of B. The time-dependence of intensity at chosen sets of values of B and L can be

Fig. 4. Contours of constant counting-rate of *Detector* 2 in the polar co-ordinate system discussed by McIlwain (ref. 7) for the normal inner radiation zone on the left and for the artificial radiation zone on the right about 6 h after the explosion. The dashed lines indicate the maximum excursions of the Earth's surface in these co-ordinates. An omnidirectional intensity of about nine penetrating particles cm^{-2} sec^{-1} will cause 1 count sec^{-1} in the detector

examined with the help of such graphs. For the magnetic shell $L=1·25$, the minimum altitudes at which $B=0·20$, 0·22 and 0·25 gauss are respectively about 540, 350 and 140 km. Hence from Fig. 3 it appears that, for this magnetic shell and this phenomenon, the intensity of electrons with $E\gtrsim 6$ MeV which mirrored as low or lower than 140-km altitude became negligible (that is, became undetectable with this instrument) within a few hours. The intensity of those mirroring at or below 350 km was greatly reduced within a few weeks, while high intensities of those mirroring above 500 kilometers will persist for months. A proper treatment of the problem using transport theory and the combined results from all detectors is being undertaken.

Comparison with *Argus* Series

Three fission devices of about 1 kiloton yield were detonated by the United States at high altitudes in August–September 1958. The resulting artificial radiation belts were less than 0·1 Earth radius thick at the equator and had peak intensities at about $L=1·7$, 2·1 and 2·2 Earth radii respectively[7].

A preliminary comparison of the shielded Geiger tube data (*Explorer IV*) on the *Argus* shells with the present data from *Detector* 2 in *Injun* shows that the initial intensity in the Johnston Island shell was of the order of one thousand times as great as that observed by *Explorer IV* on the *Argus* shells. Because *Explorer IV* sampled the *Argus* shells only at altitudes less than about 2,000 km and so considerably below their equatorial altitudes, it did not measure the peak *Argus* intensities. However, *Injun* samples the artificial radiation belt near the equator and hence near the peak intensities. A detailed comparison of the phenomena is being made.

Discussion

It appears likely that the electrons artificially injected by the Johnston Island burst will continue to be present in measurable numbers for many months on the higher-altitude shells.

As a consequence, the electron spectrum and intensity at high altitudes for magnetic shells with $L\lesssim 2$ will differ from those of the previously studied inner radiation zone for some months. A short tabulation in terms of B and L of the electron intensities now in this region has been prepared and circulated privately.

Perhaps the best overall view of the artificial radiation belt as available at present is obtained by examination of Fig. 4. One should note in particular the low altitudes to which the belt extends, and the counting-rates very much higher than those observed in the natural inner belt with the same detector. For comparison also, a similar detector has a peak counting-rate of only about 100 counts sec^{-1} in the heart of the outer radiation zone.

Invaluable telemetry reception at equatorial stations was obtained through the co-operation of Roger Tetrick of the Goddard Space Flight Centre, Rolf Dyce and George Johnson of the Stanford Research Institute and W. S. Carey of Salisbury, Southern Rhodesia.

This work was supported in part by the Office of Naval Research under contract *N9onr*93803 and by the National Aeronautics and Space Administration under grant Nos. 9233–62.

RADIOCARBON DATING

FIFTH INTERNATIONAL CONFERENCE

By Prof. H. GODWIN, F.R.S.
University of Cambridge

IN November 1954 the first representative international symposium on Radiocarbon Dating was held in Copenhagen and reported in *Nature*[1]. It was followed by others in Cambridge, Andover, Mass., and Groningen. The series has been continued by the organization of a fifth conference in Cambridge during July 23–28, under the ægis of the University Sub-department of Quaternary Research. By the courtesy of the respective governing bodies, the members were largely housed in Clare College and St. John's College, Cambridge, and meetings were held in the University Departments of Botany and Geography.

More than thirty laboratories were represented, and a large number of communications were made to the meeting by research workers from very widely separated parts of the world. We at Cambridge were very happy to welcome for the first time colleagues from the newly established Carbon Dating Laboratories in Poland and Yugoslavia.

Although there is a strong tendency to the general use of proportional gas counters, usually with a filling of carbon dioxide, it is apparent that alternative methods have by no means been totally neglected. Prof. H. R. Crane (Ann Arbor) described his considerable experience on the successful use of carbon bisulphide counters operating in the Geiger region. Representatives from the Centre d'Etudes Nucleares de Saclay (France) described their very successful development of a scintillation-counting technique. As one might have anticipated at this stage in the exploitation of the technique several contributors described their own experiences of factors leading to error in the carbon-dioxide proportional counting system, and the devices which could be used for obtaining maximum efficiency and stability, including particularly devices concerned to reduce the level of the background. Consideration was given to the theoretical consequences of counting at higher pressures than are usual, the possibility of the use of epoxy resins in counter construction and the modern improvements in the techniques of conversion of carbon dioxide to methane for use as a counting gas. The Conference listened to an account of the development at Zagreb of a method of radiocarbon assay by means of a carbon-dioxide filled ionization chamber.

The conference heard with great interest the reports of three different laboratories—Uppsala, the U.S. National Bureau of Standards, and Aldermaston, on their redeterminations of the half-life of radiocarbon. In each instance the technique used was based on mass spectrometry in combination with activity measurements in a gas proportional counter (supplemented, in one instance, by Geiger counter measurements). The three laboratories produced very similar results, which will be separately published. For the purposes of the conference it was agreed that they could conveniently be taken to indicate a best new working value of 5,730 ± 40 years. The effect of these redeterminations on the the best method of calculating and presenting radiocarbon ages was fully discussed by the Conference, with the results that are conveyed in a separate communication (see p. 984 of this issue).

Uncertainty as to the correct value for the half-life of radiocarbon is, of course, not the only unevaluated source of error in carbon dating. The method depends on the assumption that the initial radiocarbon activity of the atmosphere has been constant in the past and so far as this may be proved incorrect the method will need refinement in its application. Several laboratories have in consequence concerned themselves with activity measurements of material of known age. One important source of such material is the annual rings of trees of great age, such as redwoods and bristle-cone pines of North America and the kauri of New Zealand. The laboratories at Tucson, Pennsylvania, La Jolla, Seattle and Lower Hutt all reported measurements of this kind. Their results seem to confirm the reality of past deviations from the average atmospheric activity such as have been earlier indicated by the work of de Vries[2] and of Willis, Tauber and Munnich[3]. There seems to be some convergence of evidence of the reality of a maximum of atmospheric activity round about A.D. 1500, but there was a considerable lack of agreement between the results obtained on kauri from the southern hemisphere and those obtained from the northern hemisphere. In the discussions which followed the presentation of these results, emphasis was placed on the necessity for adequate dendrochronological assessment of the tree ring samples, and this was most evident in respect of the extremely eccentric growth of the high altitude bristle-cone pine *P. aristata*. A further source of material of known age lies in dated archæological material, particularly from Egyptian sources, the most systematic investigation of which is that being pursued in the University of Pennsylvania. There is still some discrepancy between the archæological dates and the radiocarbon determinations but the significance of the difference cannot yet be determined.

Underlying the question of the constancy of radiocarbon activity in the atmosphere, are the problems of transfer between stratosphere, troposphere and the ocean reservoirs, and several laboratories have been making use of the high concentrations of radiocarbon injected into the stratosphere by recent atom bomb tests to measure the attributes of this system. Laboratories at Los Angeles and Cambridge reported the results of preliminary sampling by aircraft from the lower stratosphere and upper troposphere, and other laboratories reported on the seasonal variations of bomb radiocarbon in the atmosphere. The Laboratories at Lamont and La Jolla reported similarly on radioactivity determinations of surface and deep water in the oceans of the world, and the inferences that these permitted regarding the turnover and exchange problems of the ocean.

The attention of the Conference was naturally directed also to a series of geochemical problems which are associated with the circumstances of deposition and preservation of material afterwards sampled for radiocarbon activity. The radiocarbon activity in certain types of meteorites was reported on as yielding no evidence of terrestrial origin. The results were also described of attempts to determine the suitability for radiocarbon age determination of snail shells from American loess deposits and of laboratory experiments based on feeding active carbon to laboratory snails. Prof. E. S. Deevey reported an extremely interesting examination of limnological problems by studying the isotopic fractionation in lakes and produced a tentative balance sheet for the carbon circulation of the ecosystem of the much-investigated Lindsey Pond. An account was given of the attempt to use determinations of the radiocarbon activity of the organic (non-carbonate) content of streams in North America to provide preliminary information on the sources of domestic, industrial and agricultural pollution of rivers. There were also reported the results of experiments to discover the extent to which woods and charcoals might take up in natural conditions contaminant carbon which could not be removed afterwards by laboratory treatment.

The concluding day of the Conference was occupied by consideration of two of the major fields of application of radiocarbon dating, namely, geological climatic phenomena and the archæological problems associated with the Neolithic culture and the spread of agriculture. From very high altitudes (5,000 m) in the Sierra Nevada of Colombia, Prof. R. F. Flint reported the early stages of inquiries comprising glacial geology, palynology and radiocarbon dating that promised ultimate correlation with European and North American events. Dr. M. Stuiver described the dating of the alternating salt and mud deposits of Searles Lake in the south-western United States, indicating an alternation of dry–warm as against cool–wet climatic episodes extending some 50,000 years back into the last (Wisconsin) glaciation. Dr. W. S. Broecker reported a close re-examination and re-dating of the famous Two Creeks site, where a forest bed beneath till has been generally thought to correspond with the mild Allerød oscillation in Europe. He produced evidence to suggest the possibility that it might alternatively be referred to the preceding Bølling oscillation. Two further contributions from Dr. M. Stuiver and Dr. I. Olsson concerned themselves with the dating of isostatic uplight in regions recently relieved from the burden of ice, namely, north-east Greenland and Spitsbergen. Dr. S. Jelgersma described the close and effective co-operation between the Geological Survey of the Netherlands and the Carbon Dating Laboratory at

Groningen in the resolution of the complex history of the progressive submergence of the Netherlands, an inquiry made particularly urgent by the need to comprehend the causes and nature of the marine incursions still being suffered in Holland The investigation of submerged peats and raised beaches in the British Isles by the Cambridge Sub-department of Quaternary Research was shown to lead to the conclusion that whereas the south-west was relatively stable, there had been isostatic uplift in the north and, in all probability, continuing tectonic subsidence in regions adjacent to the southern North Sea

Prof J G D Clark introduced a discussion on the spread of Neolithic civilization across Europe from the Middle East, stressing our changed conceptions of the absolute dating and of the routes of migration of the culture Dr H Barker indicated the nature of those British Museum dates bearing on the Neolithic period, and Dr A G Smith described the results of pollen analyses at very close intervals through two forest clearance phases at a site in Northern Ireland which had been closely carbon-dated by Dr E H Willis, the first clearances occurred before 3,500 B C and the whole episode of clearance, occupation and regeneration was shown to have occupied about 400 years, a period consistent with the ecological explanation Dr J D van der Waals described the elegant and thorough analysis of dates from the Neolithic of the Netherlands, showing among other things that within so short a time as 300 years there had been a remarkable diversification of cultural types of the Bandkeramic culture in that country Dr F E Zeuner described the significance of the British Mesolithic dates at Oakhanger, Surrey, and Torbryan in Devonshire, and commented on the Neolithic land surface of the Essex coast

A working conference of this kind has a particularly important co-ordinating function to discharge in securing the adoption of standards, furtherance of international co-operation in research, and adequate and proper publication of results The earlier conferences had already led to the annual publication of *Radiocarbon* and the constitution of a scheme for punched-card indexes of all published radiocarbon dates

It was now agreed further to support publication of a *Cumulative Index* to all radiocarbon dates published prior to the first volume of *Radiocarbon*, to seek every means to secure that all radiocarbon dating laboratories shall publish definitive date lists in *Radiocarbon*, and to secure as wide a circulation for that journal as possible The conference further urged on all authors the practice of quoting station index numbers alongside all radiocarbon dates mentioned in scholarly articles and texts

The decision not for the time being to adopt a new half-life value for radiocarbon age calculation, and to maintain statement of ages in years B P , was not reached without much discussion and some dissension, but the majority view is expressed in the communication on p 984 of this issue of *Nature*

The formal business of the conference was broken pleasantly and very instructively by a visit to the Research Laboratory for Archæology and the History of Art at Oxford, where Dr E T Hall, Dr M J Aitken and their colleagues demonstrated the variety of physical and chemical techniques now used in archæometry The apparatus in the Department of Geology for potassium–argon age determination was also demonstrated to us by courtesy of Prof L Wager Members of the Conference naturally made occasion to visit the Cambridge Radiocarbon Dating Laboratory under the guidance of Dr E H Willis, and several informal discussions on active topics were organized outside the conference programme

We owe very warm thanks for financial support to the Royal Society, the University of Cambridge, and for accommodation and hospitality to the University and the Departments of Botany and Geography We also thank our scientific colleagues and laboratory staffs in Oxford and Cambridge for all their assistance, and most particularly Dr E H Willis and Mr R Burleigh, who bore the main burden of organizing the meeting

NEWS and VIEWS

The High-Altitude Nuclear Explosion of July 9

THE U S Atomic Energy Commission and the U S Defence Department have announced that the new radiation belt created by the American high-altitude nuclear explosion on July 9 is stronger than was originally thought, and may persist for several years (see also articles by Prof J A Van Allen *et al* and Sir Bernard Lovell on pp 939 and 935 respectively of this issue of *Nature*) It was already known that the new radiation had stopped transmissions from the British satellite *Ariel* and now, on September 1, it was announced that transmissions ceased from two American satellites

It is to be hoped that those having political and/or military authority in the United States and elsewhere will take note of these serious events Although the high-altitude explosion was, for the military authorities, a legitimate test of a military situation in that they were interested in the ionospheric effects which would have been short-lived and not particularly damaging to fundamental scientific progress, it must now be recognized that a consequential and quite unintentional effect of the explosion has proved to be the trapping of the radiation in zones around the Earth

There can be no doubt that both laymen and scientists are becoming more and more worried at what appears to be grave decisions concerning upper atmosphere and space research being made mainly for military advantage or political prestige Now is the time to question the desirability of so much scientific research coming directly under the sanction of Governmental or military authorities, for it is conceivable that many scientists are unable to criticize too objectively, since they depend on political and other authorities for financial support for their work Indeed, many scientists are directly employed by Governments, and they are in no position to express concern or raise objections This all takes us back to the many times (the most recent in *Nature* of August 25, 1962) that we have pointed out the grave danger inherent in allowing science and technology to become involved in power politics

The D. and F. Guggenheim Medal for Astronomy: Prof. J. A. Van Allen

THE Daniel and Florence Guggenheim International Medal for Astronomy has, for 1962, been awarded to Prof. J. A. Van Allen, director of the Department of Physics and Astronomy in the State University of Iowa (see also p. 939 of this issue). This prize, of the value of 1,000 dollars, is awarded each year by L'Académie Internationale d'Astronautique de la Fédération Internationale d'Astronautique to a person who has made outstanding contributions to the progress of astronomy over the past five years. Last year this prize was awarded to Sir Bernard Lovell, director of the Nuffield Radio Astronomy Laboratories at Jodrell Bank.

The Marconi Co. Chief of Research: Mr. G. D. Speake

MR. G. D. SPEAKE has been appointed chief of research of the Marconi Co. He is now responsible to the Director of Research for the execution of research policy, and to the general manager for the overall administration of the Marconi Laboratories at Great Baddow, Chelmsford. This appointment follows that of Dr. E. Eastwood, the company's director of research, to the post of group director of research for the English Electric Group of Companies, of which Marconi's is a member. Mr. Speake joined Marconi's Wireless Telegraph Co., Ltd., in 1950, when he was engaged in radar systems research. In 1954 he was appointed chief of the Vacuum Physics Section of the Research Division, and two years later became chief of the Microwave Physics Group. He has been deputy chief of research since 1960. Educated at Adams Grammar School, Newport, Shropshire, and St. Catherine's College, Cambridge, Mr. Speake graduated with first-class honours in physics. Prior to joining the Marconi Co. he was instrument manager of the Plastics Division of Imperial Chemical Industries, Ltd., during 1947–50.

Electrical Engineering at Saskatchewan: Prof. A. D. Booth

DR. A. D. BOOTH, head of the Department of Numerical Automation and reader in computational methods at Birkbeck College, University of London, has been elected to the chair of electrical engineering at the University of Saskatchewan. He leaves for Canada in September. Dr. Booth came to Birkbeck College in 1946, after a period at the University of Birmingham, during which he conducted research into methods of X-ray crystal structure analysis. The large-scale calculations involved in this aroused his interest in the design of computers and, after a period of study with von Neumann at Princeton on a Rockefeller fellowship, he returned to Birkbeck College and produced the first working computer with a magnetic drum store—the *ARC*, completed in 1949. This led to a later all-electronic machine, the *APE(X)C*, which formed the basis of one of the earliest successful computers, the *Hollerith 1201*. While in the United States, in 1947, Dr. Booth was responsible for the suggestion that the translation of languages could, in principle, be undertaken by a computer. Later he conducted pioneer experiments in this field using punched-card apparatus and, with a group of active young workers, including L. Brandwood, J. Cleave and others, produced programmes for the automatic transcription of Braille and for the machine translation of technical material. Dr. Booth's recent activities have included computer applications in law and in medicine as well as in translation and in classical numerical analysis. As chairman of the committee which set up the British Computer Society as well as a member of Council of several learned societies, he has also been actively associated with the Institute for Aviation Medicine, H.M. Underwater Defence Establishment and International Computors and Tabulators, Ltd. Accompanying Dr. Booth to Canada will be his wife (Dr. K. H. V. Booth) and their two children, to all of whom go the best wishes of their many friends and colleagues in Britain.

The Nuffield Institute of Comparative Medicine: Dr. L. G. Goodwin

DR. LEONARD G. GOODWIN has been appointed the first director of the Nuffield Institute of Comparative Medicine, which is being built by the Zoological Society of London in its Gardens at Regent's Park. Dr. Goodwin will take up his appointment on January 1, 1964; before that date he will act as consultant in the planning and launching of the Institute. The Institute was founded in 1960, with the aid of a grant from the Nuffield Foundation, in order that full use could be made, for purposes of comparative medical research, of the pathological and other material derived from the species of animals in the Zoological Society's Collections. Since 1958 Dr. Goodwin has been head of the Wellcome Laboratories of Tropical Medicine, having been a member of the staff since 1939. His research has been directed towards the discovery of new substances for the treatment of tropical and other parasitic diseases in man and animals, during the course of which he has conducted numerous expeditions to tropical areas.

Harwell Variable Energy Cyclotron

A NEW azimuthally varying magnetic field cyclotron to be constructed at Harwell will provide both internal and external beams of particles at high intensities and varying energies. External beam currents and maximum energies are expected to be 100 μamp for protons (50 MeV), deuterons (25 MeV) and helium ions (50 MeV), and several μamp for a variety of heavier ions at energies up to 10 MeV per nucleon. The machine, which is similar to others recently constructed at Berkeley and at Oak Ridge, will have a 200-ton magnet with 70-in. diameter pole faces; spiral ridges (3 per pole) will be used to shape the field to enable the higher proton energies to be attained. Extensive field surveys will be made, initially with model magnets, followed by a detailed survey when the magnet is installed late in 1963. The field will be variable from 6 to 17 kG and the frequency of the dee voltage over a three-fold range. The machine will be used principally for research in the fields of radiation chemistry, radiation damage and nuclear chemistry, and will be available for use by universities. It will aid the study of radiation effects at high rates of energy deposition, and of radiation damage involving changes in a large proportion of the sample, or where an individual atom suffers several successive displacements. The Rutherford Laboratory of the National Institute for Research in Nuclear Science is responsible for the design and construction of the machine, which will be operated by the Atomic Energy Research Establishment. The building and ancillary services are the responsibility of the Authority's Southern Works Organization, clearance of the site began on August 16 and the machine is expected to operate in 1965 The total cost of machine and building is estimated to be £1,600,000

The Institute of Physics and the Physical Society

THE second annual report of the Council of the Institute of Physics and the Physical Society, presented to and adopted at the annual general meeting on July 10, records a total membership in all grades of 9,120—an increase of 400 on the previous year (Pp 24 London The Institute of Physics and the Physical Society, 1962) The number of candidates entering for the graduateship examination in 1961 greatly exceeded that expected and of the 239 candidates 64 were successful The success of the appeal for the Physics Trust Fund made in 1960 has enabled the work directed at improving the teaching of physics to be increased greatly and some £25,000 a year is now spent on educational work At the request of the Royal Society, the Council appointed a British Committee on Physics Education, with Sir Nevill Mott as chairman, to consider all aspects of physics education in Britain A committee, under the chairmanship of Prof R V Jones, was appointed to prepare a report on "Problems facing University Physics Departments" and as part of its task has prepared evidence for the Council to submit to the Robbins Committee on Higher Education (see *Nature*, 193, 911, 922, 1962)

Units and Standards of Measurement used at the National Physical Laboratory

THE units and standards of measurements used at the National Physical Laboratory, Teddington, are described in the series of booklets entitled *Units and Standards of Measurement Employed at the National Physical Laboratory* (1 *Length, Mass, Time-Interval and Frequency-Angle, Volume, Density and Specific Gravity, Gravity, Force Pressure and Hardness* 2 *Light* 3 *Electricity* 4 *Temperature* London H M S O 1*s* 6*d* net each) A completely revised third edition of the first booklet, which deals with length, mass, time-intervals and frequency, has recently been published (1962) The fundamental mechanical units of measurement together with angle and the derived units of volume, density, force and pressure in both the International System of Units and the yard/pound system are discussed, and the standards and bases of measurement used in work involving the units are indicated In addition, the absolute value of the acceleration due to gravity at the Laboratory and the measurement of hardness are briefly dealt with The most up-to-date definitions of the metre, yard and pound are given The second booklet in the series, *Light*, published in 1956, deals with units and standards concerned with photometry, colorimetry and radiation, and the third, *Electricity*, published in 1960, describes the electrical units and the standards by means of which the electrical units are determined and preserved The fourth booklet, *Temperature*, published in April this year, is an English translation of the full text of the International Practical Scale of Temperature adopted by the International Committee of Weights and Measures in May 1960 It is emphasized that the scale is not a revision of the 1948 scale but only an amended edition of the same scale, the numerical values of temperatures remaining the same as in 1948 The departures of the 1960 text from that of 1948 are summarized separately in an appendix

Teddington Products Directory

A NEW directory of products is available from Teddington Autocontrols Ltd , Sunbury-on-Thames, Middlesex (*Products Directory* Pp 24 Sunbury-on-Thames Teddington Autocontrols, Ltd , 1962) Sectionalized under appropriate headings, the publication describes the complete range of automatic control instruments manufactured by the Company Each instrument is accompanied by the relevant data sheet

Scientific Research in France

THIS comprehensive reference work on scientific laboratories in France, first issued five years ago, is arranged under international establishments, then under the academic region of Paris, followed alphabetically by those of the several provinces (Office National des Universités et Écoles Françaises *Répertoire des Laboratoires Scientifique* Pp 578 Paris Services d'Édition et de vente des Publications de l'Éducation Nationale, 13 rue du Four) The international establishments comprise the European Organization for Nuclear Research and the European Community for Nuclear Energy (Euratom), and besides names of directors and heads of divisions the information given includes numbers of research workers, scope of present work and lists of recent publications Information given for the Academic Region of Paris includes first the professors and directors in the Faculty of Science of the University and in other university departments, then the staff of the National Centre for Scientific Research, followed by corresponding information on the establishments of the Prime Minister and of the other Ministries Some information on publications is included For each of the provinces the information is arranged similarly, that for the Faculty of Science being given first, followed by information for other scientific establishments There are an abridged index of scientific staff and alphabetical indexes of subjects and equipment

Population Statistics for England and Wales . First Quarter for 1962

THE Registrar General's *Quarterly Return for England and Wales—Births, Deaths and Marriages, Infectious Diseases, Weather, Population Estimates, quarter ended 31st March 1962*, shows that the increase in births is not slackening (No 453, 1st Quarter 1962 Pp 28 London H M S O , 1962 2*s* 6*d* net) 220,710 births were registered in the first quarter, giving a crude rate of 19 4 per thousand population, as against 17 9 in the previous quarter If this increase were to continue the number of births in 1962 is likely to be between 850,000 and 875,000, that is, nearly as large as in 1947 It is likely that an increase of this size is an indication of rising marital fertility the number of births having climbed steadily, while the number of marriages has remained constant Infant mortality at 23 1 is an all-time low for a first quarter Mortality for the first quarter of 1962 shows no noticeable difference from 1961

Educational Services Incorporated

EDUCATIONAL Services Incorporated (ESI) is a private non-profit corporation devoted to research and development in education and is supported largely by grants from private foundations and the Federal Government of the United States The Corporation has grown out of the activities of the Physical Science Study Committee and has developed along two distinct lines. The first line stems directly from the Physical Science Study Committee's high-school physics course and involves further explorations in the area of curriculum reform in the United States and abroad. An example of this is the Corporation's elementary science programme. The second type of activity undertaken by Educational Services Incorporated is represented by a group such as the National Committee for Fluid Mechanics Films, an autonomous organization operating under the ægis of the Corporation and using its facilities. While funds for the support of such programmes are in most cases granted to the Corporation the groups themselves determine their own policies and operate independently. Educational Services Incorporated has now launched its first *Newsletter,* which will appear at frequent intervals (1, No. 1, May 1962). It contains accounts of its work on improving curricula as well as a detailed description of the conference held at Accra during December 17–21, 1961, to examine ways in which the teaching of mathematics could be improved and extended. *ESI Newsletter* is published from 164 Main Street, Watertown, Massachusetts.

Cretaceous Cribrimorph Polyzoa

The first monographs devoted to the strikingly beautiful Cretaceous Cribrimorph Polyzoa were published in 1921 and 1922 by Dr. W. D. Lang, who considered that the concept of orthogenesis explained their evolution. His ideas were accepted by some but challenged by others, both at that time and afterwards. In a well-illustrated work, Dr. G. P. Larwood has re-examined the sub-family Pelmatoporinae (*The Morphology and Systematics of Some Cretaceous Cribrimorph Polyzoa (Pelmatoporinae), Bull. Brit. Mus. (Nat. Hist.), Geol.*, 6, No. 1. Pp. 1–285, pls. 1–23. London: Brit. Mus. (Nat. Hist.), 1962). The material dealt with is part of two large collections made by Mr. C. T. A. Gaster, but specimens in other collections especially that of Mr. R. M. Brydone, were also examined. As a result, Dr. Larwood has reached several conclusions different from Dr. Lang's, notably on the nature of the oral spines, pelmata and pelmatidia, which, in fact, he believes to be the same as the comparable structures in Recent Polyzoa. With the wealth of material available to him, he has also merged a few genera and several species, the ranges of which have thus often been extended. Naturally, the evidence of evolution in the group is affected, and Dr. Larwood concludes that, instead of progressing along confined and determinate, distinct lines, it has taken place in a diverging plexus of variation.

Health Laboratory Services

One of the essential aims of public health in the developing countries should be the co-ordination of all types of laboratories at different levels into a single national health laboratory service that would form an integral part of the national health service. Such a system, in which clinical and public health laboratory activities are closely associated and placed under one technical direction, presents great advantages from the point of view of economy and efficiency. In its third report the World Health Organization Expert Committee on Health Laboratory Services sets out a series of recommendations on the ways and means of achieving this integration, and thus offers guide-lines for developing countries wishing to improve their health laboratory organization. (*Technical Report Series* No. 236: *Planning Organization and Administration of a National Health Laboratory Service*. Pp. 46. Geneva: World Health Organization; London: H.M.S.O., 1962. 2 Swiss francs; 3*s*. 6*d*.; 0.60 dollars.) The report opens with a description of the experience of developed countries in establishing a network of health laboratory services, and then defines the scope and functions of such services—microbiological, entomological, hæmatological, pharmaceutical and epidemiological, among others. This is followed by a full account of the many factors involved in the planning, organization and administration of a national health laboratory service in the context of long-term development programmes and in relation to the needs, health problems and resources of the country concerned.

Announcements

Dr. G. H. Metson, deputy director of research at the Post Office Research Station, Dollis Hill, London, has been awarded the Premium of the Institution of Electrical Engineers (valued at £50) for his papers "The Conductivity of Oxide Cathodes—Part 10: Spontaneous Generation of Negative Ions, and Part 12: Influence of Strontium Ion Migration on Matrix Conductivity", which appeared in the September 1961, and March 1962, issues of the *Journal of the Institution of Electrical Engineers*.

The annual convention of the American Oil Chemists' Society will be held in Toronto during October 1–4. Further information can be obtained from the American Oil Chemists' Society, 35 East Wacker Drive, Chicago 1, Illinois.

A symposium on "The Rheology of Emulsions", organized by the British Society of Rheology, will be held in Harrogate during October 1–3. Further information can be obtained from Mr. P. E. Knapp, 20 Wayside Avenue, Harrogate.

The third international symposium on "Batteries" will be held, under the auspices of the Inter-Departmental Committee on Batteries of the British Government, at Bournemouth during October 2–4. Further information can be obtained from Mr. I. B. N. Evans, 30 Fleet Street, London, E.C.4.

The national conference of the Institute of Personnel Management will be held at Harrogate during October 4–6. The theme of the conference will be "Economic Planning and Incomes Policy". Further information can be obtained from Miss W. A. Kilgour, the Institute of Personnel Management, Management House, 80 Fetter Lane, London, E.C.4.

The second Thomson Lecture of the Society of Instrument Technology will be delivered by Sir Harry Melville at the Royal Institution, 21 Albemarle Street, London, W.1, on October 4. The title of Sir Harry's lecture will be "The Effect of Instrumental Development on the Progress of Chemistry". Further information can be obtained from the Secretary, the Society of Instrument Technology, 20 Queen Anne Street, London, W.1.

The twenty-third national conference of the Council for the Preservation of Rural England will be held at Lowestoft during October 4–6. The theme of the conference will be "Post-War Developments in the Countryside". The conference is not confined to members of the Council. Further information can be obtained from the Secretary, the Council for the Preservation of Rural England, 4 Hobart Place, London, S.W.1.

BROADCASTING AND TELEVISION SERVICES IN BRITAIN

APART from its general interest, particularly its analysis of sound broadcasting and television over the past decade and its specific recommendations for future policy (see p 927 of this issue), the report of the Pilkington Committee on Broadcasting* is of considerable interest to scientists, and its usefulness is enhanced by the appendage of the report of the Television Advisory Committee, 1960 Memoranda were submitted or evidence given to the Committee by a number of scientific bodies, for example, on science broadcasting, by the London Area Science Policy Committee of the Association of Scientific Workers, the British Association and the Royal Society, which were concerned with the third television programme and the Scientific Advisory Committee, as well as with science programmes The Department of Scientific and Industrial Research submitted evidence on broadcasting of science and technology, recruitment and training of staff and the third television programme, the Institution of Electrical Engineers on research and on education and training of personnel, the National Research Development Corporation on the possibilities of band-width compression of television broadcast systems, the Nature Conservancy on natural history and conservation programmes, the Royal Horticultural Society on the need for planned instruction in horticulture, the Royal Society for the protection of birds on natural history programmes, the Scientific Film Association on educational broadcasting, treatment of medical programmes, effect of advertisements on scientific accuracy and objectivity, and the Television Society on a United Kingdom Communications Authority Co-ordinating Committee for research, line definition and colour, and educational broadcasting Evidence on educational broadcasting or special aspects thereof was also submitted by numerous other bodies, including the Royal Society of Arts, the Universities Council for Adult Education, the University of Birmingham and the Workers' Educational Association

While this list indicates well enough the range of scientific interest of the Report, the material of direct scientific interest is contained essentially in Part 4, which discusses the technical considerations, in Section 13 of Part 5, which discusses educational broadcasting, and in two short sections of Chapter 9, which discuss some particular kinds of programme Here, the forceful representations made by the Royal Society and the British Association are noted They pointed to the compelling need to present to the public the significance of science, and argued for more programmes on the varied aspects of science and technology and on the applications of developing scientific thought and knowledge, suggesting the appointment of a scientist to the senior production staff of the B B C to take charge of science programmes The Pilkington Committee thought it was no part of its task to advocate that particular subjects should find a place, or larger place, in programmes, and merely suggested that the two broadcasting organizations should consider what steps, or what additional steps, should be taken to see that these specific needs are met

On educational broadcasting the Committee observes that broadcasting is concerned with education in four ways First, through the broadcasts for schools and second through the educational broadcasts to those who have left school Third, there are programmes which, though they do not aim specifically to teach their audiences, are clearly educative, such as those on medicine and science Lastly, there is the generally educative effect of all programmes, of their diffused effect on knowledge, opinions and attitudes Apart from schools' broadcasting, however, there is no sharp break between educational and generally educative programmes

On schools' broadcasting three basic considerations were submitted to the Committee The service must be so organized as to fit into the national educational system, the purpose of the broadcasts is to help, not to replace, the teacher, and the broadcasting authorities have a duty to include education in their programmes From these considerations it follows that the broadcasting authorities, and not a central educational body, should provide the service, and because teaching is in the hands of teachers, the role of the broadcasting organizations is to be agents for the teachers All the educational bodies which gave evidence appear to accept these consequences as an essential part of the policies governing broadcasting for schools They are accepted by the B B C , but the Independent Television Authority has certain reservations about the first

There was little criticism of the programmes, and the standard of schools' broadcasts on both sound and television is high, though the Committee also concludes that there is need for more programmes, especially on television There was no criticism of either the B B C or the Independent Television Authority for not providing programmes for universities or technical colleges now, even by those who thought that such programmes should be provided in the future So far as they go—and in sound broadcasting they go a good way—the Pilkington Committee concludes that the adult educational programmes of the B B C are in themselves very good, but only a start has been made in television It finds it difficult to see how the growing demand for more television programmes can be met as long as each broadcasting organization has only a one-channel service within which to provide educational programmes as part of a comprehensive service

The idea of an educational service of broadcasting is discussed in a separate chapter, but is specifically rejected No specialized service of educational broadcasting, it concludes, should be introduced whether by a new organization or by either of the existing broadcasting authorities The Committee believes not only that the range of programmes should include educational items, the main purpose of which is specifically to teach, but also that generally educative programmes should have a right of place in all broadcasting It should also be acknowledged that almost all broadcasting should have an educative effect The development of a service specializing in education would strike at this concept of education as a purpose of all services of broadcasting, and for this reason the Committee rejected it and reasserted the principle that educational broadcasting in all its

---

[*] Report of the Committee on Broadcasting, 1960 (Cmnd 1753) Pp xii+342 (London H M Stationery Office, 1962) 18s net

forms should continue to be the responsibility of the two broadcasting authorities and provided as part of comprehensive services It recommends that the broadcasting authorities should consult with professional bodies as to the practicability of broadcasting courses of adult education of a vocational nature and that they should try every possibility of improving arrangements for consultation and liaison with the recognized adult educational organizations

The technical considerations discussed in Chapter 16 are reasonably summarized in the Committee's recommendations on this section The B B C has so far built twenty-one very-high-frequency sound stations, which serve more than 97 per cent of the population, and, within the frequencies allocated, it is impossible to provide for more high-powered stations, although low-powered relay stations or satellites could be provided, and coverage extended or improved in areas where it is now unsatisfactory There were no representations that either the B B C or the Independent Television Authority has not executed its plans for expansion as fast as was reasonably possible The Committee concludes that short-term difficulties and disadvantages of change-over do not outweigh the long-term advantages to be derived from the adoption of the 625-line definition standard recommended by the Television Advisory Committee in its report of May 1960 Accordingly, it recommends that a change in the definition standard in the United Kingdom from 405 to 625 lines be authorized forthwith A compatible service of colour television should be introduced on this standard, and the further extension of television services should be by broadcast transmission in the V H F Bands IV and V This decision will involve building very-high-frequency transmitting stations, and the Committee recommends that these transmitting stations of the B B.C and the Independent Television Authority should be co-sited and that the Postmaster-General should be given appropriate powers of direction In allotting the uncommitted frequencies in Band III, it is recommended that first priority should be given to separating the B B C 's service to Wales from that to the English regions, and the second to improving the reception of the two existing programmes and completing their coverage

CENTRAL ELECTRICITY GENERATING BOARD

NEW RESEARCH LABORATORIES

A CEREMONY to mark the official opening of the Research Laboratories of the Central Electricity Generating Board at Leatherhead was held on May 10 After an introduction by Sir Christopher Hinton, the laboratories were declared open by the Right Hon Richard Wood, Minister of Power Dr J S Forrest, director of the Laboratories, replied

Reference was made by the speakers to the fact that research on a national basis by an electricity authority was initiated in Great Britain in 1930 by the Central Electricity Board At that time the National Grid was under construction and the need for the experimental investigation of certain problems in high-voltage transmission had been recognized Small laboratories were established at Croydon and Waddon, and it was of particular interest to note, in connexion with the opening of the new laboratories, that the first member of research staff to be appointed was Dr J S Forrest, the present director

The Central Electricity Board first set up a laboratory at Leatherhead on a temporary basis in 1940 following damage by enemy air attack at the Waddon laboratories This site, adjacent to the railway line, at Kingston Road, was afterwards developed, and between 1950 and 1955 had erected on it a number of permanent buildings, including a small high-voltage laboratory During the same period facilities had been secured on nearby land at Cleeve Road for the erection of a 400-kV experimental high-voltage transmission line This land adjoined the research laboratories of the Electrical Research Association. It is on a 20-acre site adjacent to the experimental high-voltage line that the new laboratories have been erected (Fig 1) These comprise a main building with a floor area of about 100,000 square feet, a separate high-voltage laboratory of 35,000 sq ft , together with a radiographic laboratory, a staff restaurant and recreation building The buildings at Kingston Road now house the materials division of the laboratories

The total staff of the laboratories numbers about 750, of whom roughly one-third are professional engineers or scientists

The Central Electricity Research Laboratories are organized on the basis of five research divisions described as. High Voltage, Physics, Engineering, Chemistry and Biology, and Materials, and in addition there are the supporting technical and secretarial services

The lay-out of the main block of buildings has been arranged architecturally in rather an interesting way The pond for cooling water and fire fighting has been made a central feature in front of the building and over part, on a sort of isthmus on stilts, stands the lecture theatre The main block, three storeys high, is backed by two wings each two storeys high, separated by an area at present used as a car park Behind the west wing is situated the canteen, and in fairly near proximity are a temporary workshop and stores Some 150 yards away to the north is the high-voltage laboratory and not far from it a small X-ray laboratory

The ground floor of the main block houses the library, one of the drawing offices, the photography section, together with the typing room, duplicating facilities and administrative offices The first and second floors are occupied by chemistry, physics, electronics and biology laboratories, the accommodation comprising for the most part rooms ranging in size from 200 to 1,250 sq ft

The design of the two wings was influenced by experience gained in earlier laboratories This had demonstrated the necessity of providing fairly large areas of floor space on ground-level on which heavy experimental plant could be erected Large-scale 'test rigs' require access to the major engineering services, suitable arrangements of foundations, head room, crane facilities and access and transport facilities Indeed, the provisions required are similar to those of the 'test bed' of a manufacturer of machinery or electrical plant One such area is provided

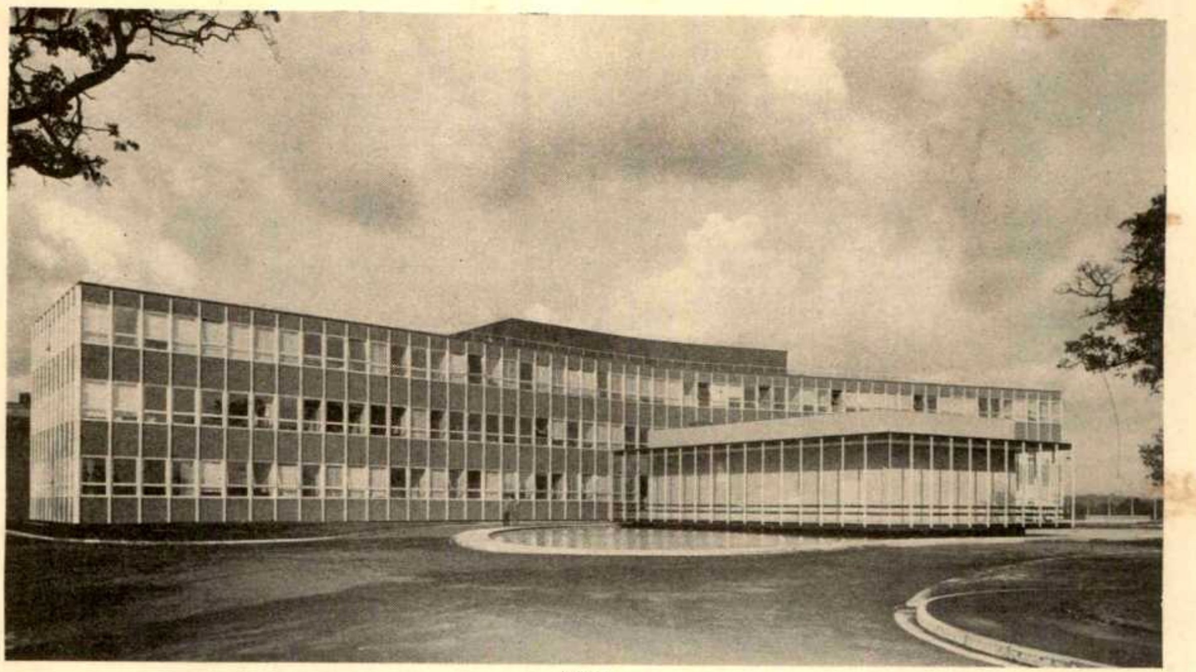

Fig. 1

in each of the wings, the dimensions being 200 ft. by 60 ft. These areas are flanked by laboratories and small rooms on two floors.

The high-voltage building has a total working area of 35,000 sq. ft., the main bay of the laboratory having an area of 12,000 sq. ft. and a height of 70 ft. The planning of these laboratories was completed in 1958, and parts of the new buildings were completed and occupied by January 1961. By the end of the year all the buildings were complete and in full operation.

Work in progress was demonstrated in all five Divisions of the laboratories. Terminating at the High-Voltage Laboratory is a new experimental line, a double-circuit single-phase line which will be used to study line corona and insulator losses and radio noise from multiple bundle conductors at system voltages up to the equivalent of 840 kV three phase. The equipment of the High-Voltage Laboratory itself will provide power frequency voltages up to 1·2 MV r.m.s. and impulse voltages up to 4 MV peak. Studies of the breakdown and deterioration of the dielectrics used in transformers, switchgear and cables form an important part of the work of this division. In addition, the division investigates the current-carrying capacity of conductors for overhead lines and substations, and for this purpose equipment is available for producing currents up to 100 k.amp. A particularly interesting group of investigations in the same division concerns magnetohydrodynamic generation. These comprise a 2 MW oil-burning jet, a shock-tube experiment and a plasma-jet experiment together with a mercury closed cycle equipment.

In the Physics Division work on solid-state physics deals with the fundamental electric and electronic properties of new materials which are likely to have application in the supply industry, for example, semi-conducting oxides, liquid semi-conductors and metals in the super-conducting state. Associated with this work is apparatus for the growth and preparation of single crystals, zone melting apparatus, and there is an automatic recompression system for the recovery of helium gas evolved during experiments using liquid helium. Localized electron states in solids are being studied by means of an electron spin resonance spectrometer.

The mathematical work of the Division is naturally much concerned with the expression of physical problems in mathematical forms suitable for analytical or numerical solution. The resources of the Board's Computing Centre situated at Gordon House in London are utilized for numerical computation. Typical of the physical problems which are encountered are: the diffusion of gases in the atmosphere, the scattering of electromagnetic waves by plasma and the oscillation of a freely suspended catenary in the atmosphere. There is, in addition, a range of important problems concerned with the automatic control of transmission line networks and of associated generating equipment.

In the laboratories as a whole there is a central instrument service which is provided by the Physics Division. For the most part, existing commercial equipment is utilized but a substantial effort is devoted to the development of new instruments and systems. The non-destructive examination of materials and of components is another of the Physics Division's responsibilities and the equipment provided for this purpose includes apparatus for the generation and detection of ultra-sonic waves and X-ray equipment giving complete coverage within the range 10–400 kV.

Mechanical and civil engineering, including specialized sections dealing with fluid dynamics and heat transfer, constitute the main fields of activity of the Engineering Division. A long-bed tensile testing machine provides facilities for the testing of transmission line conductors in lengths up to 77 ft. and heating current up to 3,000 amp can be circulated through the specimen. An equipment has been built for the tri-axial testing of concrete at elevated temperatures. This research relates to pre-stressed concrete pressure vessels. Strain-gauge measurements naturally play an important part, and considerable effort is devoted to the study of special techniques associated with the various uses of strain gauges. One such investigation concerns the practicability of using resistance strain-gauges for measuring the vibrations of turbine blades under service conditions. There is a vibration testing laboratory in which, at present, static vibration tests are being carried out on models of steam turbine-blading in order to determine their resonant modes.

Photo-elastic analysis is applied to the investigation of stresses in pressure vessels, steam headers and fuel element cans.

Measurements of particle size and other studies related to powders and dusts are carried out on materials such as fly ash and pulverized coal.

The work of the Division of Chemistry and Biology ranges from a group of researches on fuel cells to studies in marine and fresh-water ecology. The effects of power station operation on the ecology of marine and fresh-water organisms is a matter of increasing importance.

The analysis of flue gases, an important and traditional chemical measurement in thermal power stations, is now carried out by gas chromatography. Research is in progress on apparatus for effecting remote control of combustion by means of a computer handling automatically data provided by a gas chromatograph. The efficiency of different absorbent materials in extracting sulphur dioxide from flue gases is a related topic.

Internal corrosion in boilers is studied with the help of an experimental boiler, and work is also in progress on the fouling and corrosive effects of combustion products on the fire-side of boilers.

Although the scope of the Materials Division is in no way restricted to metals, the main effort is at present directed to metallurgical research, especially to performance at elevated temperatures in particular applications. Mechanical testing, involving high-temperature tensile, creep and fatigue tests, thus plays an important part. The effects of welding, stress relieving and other fabricating procedures are also studied. Much attention is devoted to austenitic steels used at temperatures above 550° C. Materials which may be of importance in high-temperature equipment for the direct generation of electricity are also the subject of investigation. Magnetohydrodynamic generation, for example, will require insulating duct materials and conducting electrode material capable of withstanding temperatures in excess of 2,000° C for long periods. Silicon carbide has potential importance in high-temperature rectification, and apparatus has been designed to grow single crystals of this material epitaxially.

The supporting technical services of the Laboratories were illustrated by an interesting series of exhibits in the central workshops and drawing offices. Machine and assembly work, profile cutting, welding, chassis wiring, armature rewinding and cable jointing were in progress.

Design and workshop drawings for mechanical and electrical equipment were shown in the drawing offices together with illustrative work.

In the photographic section examples included high-speed still and ciné photography, photomicrography and colour photography.

The opening of these new Laboratories serves further to demonstrate the will of the supply industry to maintain and to improve its position by its ability to absorb and to apply new scientific knowledge and, in addition, to make its own contribution to fundamental advances. It is important to realize that the Central Electricity Research Laboratories constitute only one of a group of major research projects operated by the Central Electricity Generating Board. The Berkley Nuclear Laboratories are exclusively concerned with the special problems of nuclear power stations. A further research station, designed to undertake large-scale experiments in the field of generation and transmission, is being established at Marchwood on Southampton Water. In addition, each of the five regions of the Generating Board has a regional research organization devoted primarily to the solution of problems in the operation of power stations and of the Grid System in its own area. All these organizations, with a research staff totalling some 1,300, contribute to the research effort devoted to improving electricity supply.

J. GREIG

ROTHAMSTED EXPERIMENTAL STATION

REPORT FOR 1961

THE diversity of modern agricultural research is well exemplified in the annual report of the Rothamsted Experimental Station for 1961*. It covers the activities of the twelve research departments at Rothamsted, the farms there and at Woburn, the experimental stations at Woburn and at Dunholme and the work of the Soil Survey of England and Wales. Of the 296 pages in the report, more than 200 describe investigations actually in progress or just completed and a short review can scarcely do justice to the year's work of this, Britain's premier, agricultural research station.

Of topical interest and importance are the results of a ley-arable rotation experiment designed to assess the effect of the ley on soil fertility and the performance of subsequent crops. Since Stapledon so forcefully and successfully advocated the use of the ley before and during the Second World War, it has been widely assumed that the benefits were automatic. Farm practice has often seemed to confirm this, but in fact critical experimental data, either for or against, are singularly few. For several years the Rothamsted experiment has been running in two parts, one on a field ploughed from old pasture and the other on land long under an arable rotation. The test crops were wheat, potatoes and barley, and the results, apart from a few interesting but minor variations, show that no definite improvement in yield has followed the ley that cannot, just as easily, be secured by the use of fertilizer in a purely arable rotation. Ley-arable rotations do not lend themselves very readily to really critical experimental control, and the danger of generalization from one set of experiments is obvious, but the work is valuable just because of this. We may well have overstated the case of the ley as a universal panacea and a well-based re-appraisal will certainly do no harm.

---

* Lawes Agricultural Trust. Rothamsted Experimental Station, Harpenden. Report for 1961. Pp. 296. (Harpenden, Herts: Rothamsted Experimental Station, 1962.) 15s.

Another classical concept in agriculture is the role of farm-yard manure in maintaining and increasing soil fertility Again, farm experience would leave little doubt as to its value, but the reasons for this may not be those we have always assumed The Chemistry Department has continued its experiments to show just how farm-yard manure affects crops, and an interesting and essential development is a study of liquid manures resulting from the intensive methods of stock management now being practised Liquids from piggeries were analysed and shown to be rich sources of N P K, for example 1,000 gal of one sample supplied 90 lb nitrogen, 70 lb phosphorus pentoxide and 70 lb potassium monoxide The disposal of large volumes of such material is a major practical problem on farms to-day, but its value is such that new methods of conservation and disposal must be devised so that this potentially rich source of plant nutrients may be used to full advantage

The work being carried out by the Botany Department is concerned with matters ultimately related to crop yields The physiology and distribution of weed seeds and the competitive activities of the resultant plants have been studied, while the long-term investigations on the physiology of growth and yield continue to provide useful information One of the major advances in post-war agriculture has been the development of spring varieties of wheat almost the equal in performance to their winter counterparts An analysis of the photosynthetic processes in varieties of wheat suggested that the greater efficiency of grain production in Capelle and Jufy I was attributable to increased photosynthesis in the ears of these varieties as compared with Squareheads Master or Atle Studies such as these provide the plant breeder with vital information that may well open up new lines of cereal development Two new records are reported from the Plant Pathology Department For the first time blight lesions have been found on a potato tuber without any sign of the disease appearing above ground on the parent or neighbouring plants This adds to our scanty knowledge of what actually happens in the earliest stages in the development of this well-known disease For the first time, too, *Pithomyces chartarum*, the mould responsible for facial eczema in sheep in New Zealand, has been found in several areas in the Home Counties In New Zealand the disease is a serious one, the organism being produced in enormous quantities, especially on mown grass The discovery of the fungus in Britain is a direct, if unwelcome, consequence of the utilization of aerial spore-trapping procedures developed at Rothamsted

Rothamsted does not restrict its services to agriculture in Great Britain Overseas problems are studied the report lists the advisory visits, and secondments abroad, of members of staff. Of interest in this connexion is the work of the Biochemistry Department in devising and establishing leaf protein production units for use overseas. At home the Dunholme Field Station is now closed, and the sugar beet work will be carried on from a new base, Broom's Barn It is to be hoped that Dr R Hull and his staff will there find increased scope to continue the excellent and valuable work that has meant so much to the beet industry in Britain

J H WESTERN

CALCIUM REQUIREMENTS BY HUMAN BEINGS

MORE people fail to receive the amounts of calcium normally recommended as necessary than of any other nutrient, yet there is little convincing evidence of any disabilities specifically attributable to deficiency of calcium In many parts of the world only limited opportunities exist for the intake of the recommended amounts, and this has led to suggestions for the widespread fortification of foods with calcium This can be both expensive and technically difficult, and in the long run—according to a joint Food and Agriculture Organization/World Health Organization Expert Group on Calcium Requirements—nutritional improvements ought to be met through a better basic diet and not only by supplementation of this kind (*WHO Chronicle*, 16, No 7, July, 1962)

No supplementary calcium should be given without first obtaining reliable information about the calcium needs of different population groups Contrary to what has sometimes been believed, the development of rickets and dental caries is largely independent of the intake of calcium In adult life no clear signs of calcium deficiency in men have ever been described in any part of the world In women, among populations where the intake of calcium is habitually low, repeated pregnancies and long lactations may be associated in some regions with the development of osteomalacia, though this is not solely due to the low intake of calcium In some parts of northern India, for example, osteomalacia is frequent with higher intakes of calcium, whereas it is rare in southern India, where the intake is lower It would seem that if the intake of vitamin D is satisfactory, osteomalacia is not a problem even for women whose intake of calcium is low—though a low intake of calcium may be an exacerbating factor The common osteoporosis of old age is thought by some investigators to be associated with calcium deficiency but by others to be more related to endocrine disturbances Nor does present knowledge support the view that a low intake of calcium is necessarily prejudicial to normal physiological function, although certain pathological conditions, mostly rare, do exist in which increased intake of calcium may be advisable Among conditions in which calcium deficiency may play a part are the osteopathy of premature infants, various syndromes involving subnormal calcium absorption, such as steatorrhœa and certain forms of chronic renal damage with or without calciuria, and senile osteoporosis

In making recommendations on calcium needs, the Expert Group defined the minimum requirement of calcium for adults as the smallest amount that will maintain health and keep the body in calcium balance when the diet is otherwise adequate and the vitamin D status is satisfactory The available evidence, however, does not permit the specification of any particular figures for minimum adult requirements, for disorders often attributed to calcium deficiency have not been observed in large populations habitually subsisting on intakes of only 300–400 mg a day, and it has been shown that adults can successfully adapt themselves to intakes of 400–500 mg and even less

PENICILLIN-LIKE SUBSTANCES IN PREPARATIONS OF 6-AMINOPENICILLANIC ACID

By F. R. BATCHELOR, M. COLE, D. GAZZARD and G. N. ROLINSON
Beecham Research Laboratories, Ltd., Brockham Park, Betchworth, Surrey

EXAMINATION of preparations of crystalline 6-aminopenicillanic acid (6-APA) (refs. 1 and 2) has revealed the presence of three substances of a penicillin-like nature which have not been described hitherto. Two of these substances show substantial antibacterial activity, and were apparent on bio-autographs, while the other shows almost no activity and was located by continuous paper electrophoresis and assay by the hydroxylamine method[2].

6-APA itself shows a relatively low order of antibacterial activity[3,4], and, unless high concentrations are involved, this compound cannot be detected on bio-autographs without first reacting with a suitable acid chloride to form a penicillin. However, when relatively high concentrations of 6-APA were subjected to paper chromatography such that the amount of material on the chromatograms was sufficient to give rise to a zone of inhibition on bio-autographs without prior acylation, not one, but two zones of inhibition were seen. One of these zones was identified as being due to 6-APA itself. This was done by spraying the chromatograms with phenylacetyl chloride prior to development on the seeded plate[2]. As a result of this step the size of this zone of inhibition was very greatly increased, but, in contrast, the other zone on the bio-autograph was unaffected by the acylation. The solvent system used was butanol/ethanol/water, 4:1:5 top layer, and the test organism was *B. subtilis*. In this chromatographic system the unidentified compound ran with a lower R_F value than 6-APA. On the other hand, using the solvent system butanol/acetic acid/water, 60:15:25, the unidentified substance ran with a higher R_F value than 6-APA. These R_F values are given in Table 1.

Table 1. R_F VALUES FOR FACTOR 1 AND 6-AMINOPENICILLANIC ACID

Solvent sytem	Factor 1	6-APA
1	0.05	0.14
2	0.61	0.44
3	0.36	0.47

Solvent 1, butanol/ethanol/water, 4:1:5 top layer
Solvent 2, butanol/acetic acid/water, 60:15:25
Solvent 3, butanol/pyridine/water, 1:1:1

This unidentified substance, referred to here as 'Factor 1', has been found to be present in all preparations of 6-APA examined so far, including 6-APA isolated from fermentations of *Penicillium chrysogenum*[1,2], 6-APA prepared by enzymatic hydrolysis of phenoxymethylpenicillin[5,6] and 6-APA prepared by enzymatic hydrolysis of benzylpenicillin[5,7-9]. It would therefore seem unlikely that Factor 1 is an impurity carried through with the 6-APA during the extraction procedure. Factor 1 is an acid-stable compound, and cannot be detected in either the benzylpenicillin or phenoxymethylpenicillin from which the 6-APA was obtained. Furthermore, there is evidence that Factor 1 is formed from 6-APA in solution. Results are shown in Table 2 for the antibacterial activity of 6-APA solutions maintained under different conditions of temperature and *p*H over periods of 24 and 48 h. The activity was estimated by cup-plate assay against *Bacillus subtilis* and expressed in units of benzylpenicillin. It will be seen that over a period of 48 h at *p*H 6.0 and 37° C the antibacterial activity of the solution increased more than ten-fold, notwithstanding the fact that hydroxylamine assay of total β-lactam ring indicated a loss of 15 per cent. Paper chromatography showed that this increase in activity was due to an increase in the Factor 1 content of the solution.

6-APA and Factor 1 can be separated by paper electrophoresis using a pyridine/acetic acid buffer, *p*H 4.3, prepared by adding pyridine to 0.05 M acetic acid. In experiments using 17 V/cm for 4 h, 6-APA remained at the point of application, while Factor 1 migrated 6 cm towards the anode. Partially purified Factor 1 material was prepared by incubating a solution of 6-APA at *p*H 6.0 and 37° C for two days, and almost all the 6-APA was then removed by passing the solution through a column of cation exchange resin ('Amberlite *IR* 120 H') giving an acid effluent which was neutralized with sodium hydroxide and freeze-dried. This material was then subjected to preparative continuous electrophoresis using a Beckman Spinco apparatus run at 800 V with a residence time of 2 h. Before application to the electrophoresis curtain the material was made up as a 5 per cent solution in distilled water, de-salted electrolytically and diluted 2 in 5 with the pyridine/acetic acid buffer already referred to. Factor 1 was detected in the fractions by assay for antibacterial activity using *B. subtilis* as test organism. 6-APA was detected in a similar manner but only after first reacting with phenylacetyl chloride to convert to benzylpenicillin. It will be seen from Table 3 that 6-APA was obtained in Fraction 11, and Factor 1 in Fractions 17–20. Although the 6-APA content of the material fractionated in this way was too low to permit assay by the hydroxylamine method, the Factor 1 present could be estimated readily and is expressed in Table 3 as benzylpenicillin equivalents. The hydroxylamine assay method also revealed the second unidentified compound as being present in Fractions 24–29. This second compound, referred to here as 'Factor 2', showed no antibacterial activity either before or after phenylacetylation, but in terms of benzylpenicillin equivalents by hydroxylamine assay the amount present was greater than that of Factor 1.

Freeze-dried preparations of both Factor 1 and Factor 2 were obtained by pooling the relevant fractions above. Assuming both compounds to have a molecular weight similar to benzylpenicillin the purity of the preparations appeared to be of the order of 30 per cent. Hydroxylamine and manometric

Table 2. INCREASE IN ANTIBACTERIAL ACTIVITY OF SOLUTIONS OF 6-AMINOPENICILLANIC ACID MAINTAINED UNDER DIFFERENT CONDITIONS OF TEMPERATURE AND *p*H

Time (h)	Antibacterial activity expressed as units of benzylpenicillin/ml				
	*p*H 7 5°C	*p*H 7 20°C	*p*H 7 37°C	*p*H 6 37° C	*p*H 8 37°C
0	5	5	5	5	5
24	7	10	26	52	17
48	7	14	28	60	17

Solutions of 6-APA at a concentration of 2 per cent were adjusted to *p*H values of 6, 7 and 8 and maintained at 5, 20 or 37° C assay[10] gave similar results for both Factor 1 and Factor 2, which is of interest since 6-APA itself is not amenable to manometric assay[2]

During attempts to prepare larger quantities of material rich in Factor 1 and Factor 2 by incubating a 15 per cent solution of 6-APA at 37° C overnight, most of the residual 6-APA was precipitated by adjusting the *p*H to 4 3 prior to stripping out further 6-APA by ion-exchange resin as already described Examination of this precipitate revealed that it contained a third unknown substance with antibacterial activity which migrated 1 cm towards the cathode (at *p*H 4 3, 17 V/cm) Control electrophoresis tapes using glucose revealed that this movement was entirely due to electro-osmosis and over a range of *p*H 2–8 Factor 3 would appear to have zero zeta potential As with Factor 1, the initial *p*H of the 6-APA solution affected the yield of Factor 3 With 6-APA kept between *p*H 1 and *p*H 5 no Factor 3 could be detected At *p*H 6 a small zone could be seen, but the greatest yields were obtained over the range *p*H 7–9 There is some evidence that Factor 3 is not, in fact, a single substance, but is a complex mixture of several substances When Factor 3 was subjected to two-dimensional separation, using paper electrophoresis in one direction to separate it from traces of 6-APA, Factor 1 and Factor 2 which contaminated the preparation, followed by paper chromatography using butanol/acetic acid/water in the other direction, the Factor 3 zone separated into at least four distinct zones The size of the zones, revealed by bio-autographs on agar plates seeded with *B subtilis*, decreased with the R_F values, which were 0 3, 0 23, 0 17 and 0 14.

Factor 1, Factor 2 and Factor 3 are readily destroyed by *B cereus* penicillinase and, like 6-APA, the three compounds are acid-stable

Results for the antibacterial activity of 6-APA, Factor 1 and Factor 2 are given in Table 4 The figures for Factor 1 and Factor 2 have been corrected for the purity of the preparation on the basis of hydroxylamine and manometric assays assuming a molecular weight equal to that of benzylpenicillin It will be seen that Factor 2 shows a very low order of antibacterial activity and is not likely to contribute significantly to the activity shown by preparations of 6-APA which contain this material On the other hand, Factor 1 shows considerable activity, notably against the Gram-positive bacteria Against *Sarcina lutea*, *B subtilis* and also *Neisseria catarrhalis*, Factor 1 appears to be about fifty times as active as preparations of 6-APA, and from the M I C (minimum inhibitory concentration) values for 6-APA it would therefore appear that the amount of Factor 1 present in the 6-APA samples could not be more than about 2 per cent Such a concentration of Factor 1 would, in effect, contribute all the Gram-positive activity which preparations of 6-APA display Against the Gram-negative bacilli, however, Factor 1 shows relatively little activity and with several organisms it is actually less active than 6-APA Consequently, it would seem that the activity shown by preparations of 6-APA against Gram-negative bacilli is, in fact, due to 6-APA and not to the impurity of Factor 1 This is certainly true if the content of Factor 1 in 6-APA is of the order of 2 per cent or less, since this amount would not make any detectable contribution to the Gram-negative activity of 6-APA

* Penicillin resistant

No solid Factor 3 preparation has yet been obtained free from 6-APA, Factor 1 and Factor 2, and no quantitative information of antibacterial activity could be obtained From results where electrophoresis tapes were placed on agar plates seeded with a variety of organisms, Factor 3 appears to have a typical penicillin spectrum of high Gram-positive and low Gram-negative activity

It would appear, therefore, that 6-APA does possess antibacterial activity which is distinct from that exhibited by the compounds referred to here as Factors 1, 2 and 3

We thank Mr C Reading and Mr D Duke for technical assistance, and Mrs Shirley Stevens and her staff for the M I C determinations

Since this article was prepared, the paper by Grant *et al* [11] on poly-6-aminopenicillanic acid has come to our notice Although the substance reported by them may well be related to the Factors 1, 2 and 3 reported here, there are obvious differences in electrophoretic migration and antibacterial activity, and, furthermore, Factors 1, 2 and 3 are all readily dialysable under the conditions where poly-6-aminopenicillanic acid is retained

CORRELATION OF OXIDATION-REDUCTION CHANGES OF INTRACELLULAR REDUCED PYRIDINE NUCLEOTIDE AND CHANGES IN ELECTROENCEPHALOGRAM OF THE RAT IN ANOXIA

By DR. BRITTON CHANCE and BRIGITTE SCHOENER

Johnson Research Foundation, University of Pennsylvania

A MICROFLUOROMETRIC method for the recording of the kinetics of oxidation-reduction changes of intracellular pyridine nucleotide in localized areas of tissue has been described[1,2]. One paper describes in detail the controls which have been used to evaluate the possible interference due to the oxyhæmoglobin–hæmoglobin change[2]. Another paper describes how emission spectra of localized areas of the tissues can be recorded by a modification of the microfluorometer used[3].

The purpose of this article is to correlate changes in electroencephalograms with changes in the intracellular oxidation-reduction state.

A rat, weighing approximately 250 gm., was anæsthetized with urethane (1.0 mgm./kgm.). A 20 mm.^{2} area of the cortex was exposed either with a high-speed trephine or a dentist's burr. (A number of these operations were carried out by Dr. W. S. Masland of the Department of Physiology.) The dura was left intact, and in successful preparations the blood-free field was obtained. The trachea and femoral vein were cannulated. The inspired gas was controlled with a gas-mixing apparatus. The potential changes were recorded with a 1-mm. silver ball in contact with a cortical area directly adjacent to the aperture and displaced from it by 0.5–1 mm. The recordings were monopolar, the reference electrode being the ear pins of the head holder. The frequency pass of the recordings at the half-power voltage points was 6–25 c.p.s. The microscope was focused on an area containing a minimum of visible blood vessels. The microfluorometer made use of a 1-kW. mercury arc, a 366 mμ primary filter, and a secondary filter giving a broad pass band (400–520 mμ), peaking at 450 mμ. Optical fields of 17 and 30μ were used.

Fig. 1 illustrates temporal relationships between fluorescence and potential changes. Time increases from left to right, and a fluorescence increase is indicated by a downward deflexion. In view of other experiments, the increased fluorescence is attributed to a reduction of intracellular pyridine nucleotide, to which the mitochondrial material contributes a major part[2]. The deflexion corresponding to a 20 per cent increment of total fluorescence is indicated as is the potential change corresponding to 1 mV. The rat, initially breathing 20 per cent oxygen and 80 per cent nitrous oxide, is transferred to 100 per cent nitrous oxide at the first event marker. Six seconds thereafter there is a 4 per cent decrease of fluorescence which reaches a maximum 12 sec. after the transfer to 100 per cent nitrous oxide. During this interval, the synchronous activity on the cortex increases somewhat[4]. At 12 sec. after the transfer to nitrous oxide, the fluorescence intensity increases over an interval of approximately 20 sec., and the electrical activity continues at a diminished level until the pyridine nucleotide reduction reaches approximately 80 per cent of the maximum value recorded. Thereafter, electrical activity can no longer be observed. At very nearly the same time, breathing can no longer be observed. Approximately 20 sec. after the cessation of breathing, the inspired gas is returned to 20 per cent oxygen and 80 per cent nitrogen, and the animal is ventilated manually two or three times. Approximately 5 sec. afterwards, the fluorescence intensity abruptly decreases and breathing is resumed. The fluorescence trace shows an overshoot in the recovery from anoxia. In the final phases of recovery, electrical activity can be observed on the cortex, and a few minutes after the end of the record illustrated here, electrical activity similar to that observed in the beginning of the experiment is observed.

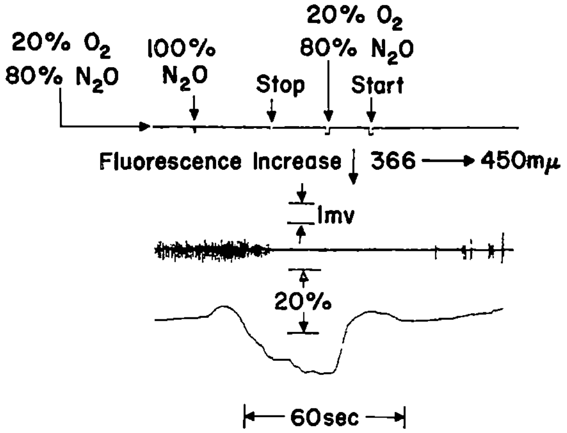

Fig. 1. Microfluorometer focused on 30-μ area in pre-occipital cortex. 1-mm. diameter monopolar electrode is placed approximately 1 mm. away from the observation point. The top trace represents the moments of changing the concentration of the inspired oxygen. In addition, the moments of starting and stopping breathing are indicated. The middle trace gives the electroencephalogram (6–25 c.p.s. band-width) and the voltage calibration. The lower trace gives the fluorescence changes with an increase indicated by a downward deflexion. The calibration mark represents a 20 per cent change of the total fluorescence emission, 366 mμ excitation, 450 mμ measurement

The most characteristic feature of this type of record is that both electrical activity of the cortex and breathing continue until reduction of pyridine nucleotide in anoxia has very nearly reached its maximum value. Two other characteristics of the record are the cyclic decreases of fluorescence on transfer from oxygen to nitrous oxide and vice versa.

If, instead of suddenly transferring the inspired gas from 20 per cent oxygen to zero as in Fig. 1, the inspired gas is slowly diminished as in Fig. 2, the sequence of events can be depicted somewhat more clearly. There the inspired gas as monitored by the Pauling oximeter is changed from 20 to 6 per cent and is accompanied by only slight reduction of pyridine nucleotide. The electrical activity increases but falls to a minimum at about 5.5 per cent inspired oxygen. Thereafter, there is a marked increase of electrical activity and a clear increase of pyridine nucleotide reduction. The electrical activity then achieves a very large amplitude as the inspired gas falls from 3 to 2.5 per cent and the pyridine nucleotide level becomes even further reduced. There is an abrupt halt to electrical activity, followed 6 sec. later by a cessation of breathing and a final increase of pyridine nucleotide reduction to its plateau value 15 sec. after cessation of breathing, 20 per cent oxygen is administered, and 6 sec. thereafter an oxidation of reduced pyridine nucleotide is observed together with evidences of very small electrical signals. As the pyridine nucleotide level rises toward a higher degree of oxidation, the electrical activity starts off at a very high level, which is maintained until the end of the recording.

A characteristic feature of this recording is that electrical activity ceases when the pyridine nucleotide level is about 70 per cent reduced, a smaller value than in the previous experiment.

With a fresh preparation in which only a few cycles of aerobiosis and anoxia have been carried out, and in which the transition from aerobiosis and anoxia is made rapidly, a continuation of localized electrical activity can be observed for 10 or more sec. after the pyridine nucleotide reduction has reached its maximal value. Such a record is indicated in Fig. 3. In this experiment, there is no initial diminution of fluorescence following the transfer from 100 per cent oxygen to 20 per cent oxygen plus 80 per cent nitrous oxide. The electrical activity is observed clearly to persist at 20 sec. after the pyridine nucleotide reduction has reached the maximal value and breathing can no longer be observed. In this record, the resumption of electrical activity can be observed at about the same time as reoxidation of the reduced pyridine nucleotide occurs after the changing from 100 per cent nitrous oxide to 20 per cent oxygen, plus 80 per cent nitrous oxide.

These records illustrate two types of correlations between the electrical activity of the cortex and the degree of reduction of pyridine nucleotide caused by the transition from aerobiosis to anoxia. In an experiment in which several cycles of anoxia have occurred, the sudden change from aerobiosis to anoxia causes electrical activity to cease simultaneously with an 80–90 per cent completion of the pyridine nucleotide reduction. A similar effect may be obtained if the animal proceeds in a number of stages to lower and lower oxygen tension. On the other hand, if a fresh animal makes a rapid transition from aerobiosis to anoxia, the electrical activity can be observed to persist after the completion of the pyridine nucleotide reduction.

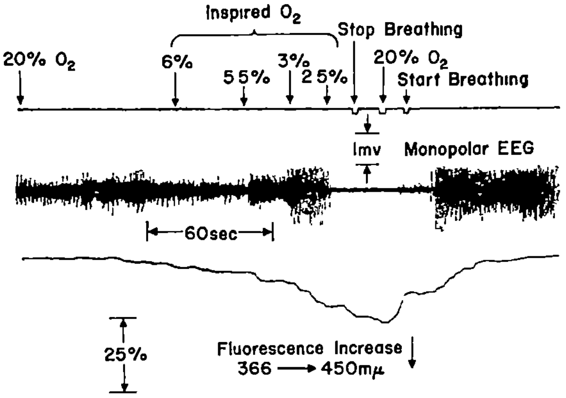

Fig. 2. Correlation between EEG and pyridine nucleotide reduction in the slow transition from aerobiosis to anoxia. The convention of recording is the same as that described in Fig. 1, except that the top trace includes the measurements of inspired oxygen concentration according to the Pauling oximeter.

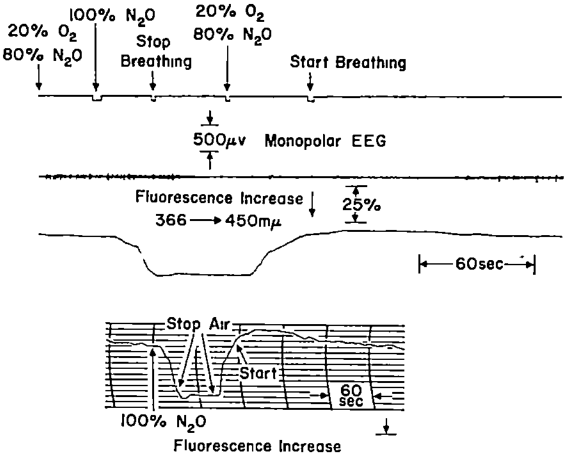

Fig. 3. Correlation between EEG and pyridine nucleotide reduction in a rapid transition from aerobiosis to anoxia. The recording follows the pattern described in Fig. 1, except that the time-course of the fluorescence change over a 7-min. interval is indicated by the insert below at the bottom of the figure.

It is appropriate to use the increase of fluorescence intensity in anoxia to a plateau value as an indication of the cessation of oxidative phosphorylation. Any electrical activity following this time must depend on stores of high-energy intermediates. The fact that these can be exhausted by repeated cycles of anoxia or by prolonged decrease of oxygen tension to anoxia is consistent with this view. Stores of high-energy intermediates consist not only of creatine phosphate but also of high-energy intermediates of the mitochondria themselves. Variations in the interval over which electrical activity can be maintained after the completion of pyridine nucleotide reduction may reflect changes in the level of such high-energy intermediates and be useful in their assay *in vivo*.

An interpretation of a diminution of fluorescence observed following the transition from oxygen to nitrogen and vice versa (Fig. 1) can be given in terms of the effects of adenosine diphosphate and phosphate on the steady state concentration of mitochondrial pyridine nucleotide[5]. We have found that activation of respiratory metabolism by an increase in the concentration of these compounds causes the oxidation of mitochondrial reduced pyridine nucleotide. Such increases in phosphate or phosphate acceptor could easily be a consequence of the increased electrical activity observed in hypoxia (Fig. 1). In Fig. 2 the oxygen tension was sufficiently low at the time when increased electrical activity occurred that no clear-cut diminution of fluorescence could be observed. The overshoot following the administration of oxygen is attributed to the accumulation of ADP and phosphate in the anoxic interval. It is hoped ultimately to be able to relate the phosphate potential to the electrical activity.

It is noteworthy that a re-oxidation of pyridine nucleotide is a necessary (Fig. 2) but not a sufficient condition (Fig. 1) for the resumption of electrical activity.

It is the primary purpose of this article to give a preliminary survey of a few types of correlations between localized electrical activity of the cortex and the kinetics of oxidation and reduction of pyridine nucleotide in the transition from the aerobic to the anoxic state and vice versa These results show a dependence of electrical activity and the oxidation-reduction state of pyridine nucleotide providing reserves of high-energy compounds have previously been depleted

EVALUATION OF ANTIBIOTIC SYNERGISM

By Dr. DEBORAH KAPLAN and Dr. WALTER KOCH
Department of Microbiology and Public Health,
Chicago Medical School

ONE established method of determining antibiotic sensitivity consists in inoculating test tubes containing broth and antibiotic, and noting the smallest concentration of the antibiotic at which no visible growth occurs after an incubation of 18–24 h[1] If this amount is below the concentration attainable in the blood[2,3], the antibiotic may be useful in therapy There is a shortcoming in this method if the doses are not closely spaced, there is little certainty that the dose recorded really is the smallest which inhibits growth It has been found that, over a small range, logarithms of doses of antibiotics and logarithms of percentage transmission readings of bacterial growth are directly related As absence of growth is indicated by a percentage transmission reading of 100, the log of which is 2, the log of the smallest dose which would prevent growth can be estimated by extrapolation from two doses causing partial inhibition Let D_1 be the smaller dose, causing the percentage transmission reading R_1, D_2 and R_2 the corresponding values for the greater dose, and D_A the smallest dose causing absence of visible growth, then

$$\log D_A = \log D_2 + \frac{2 - \log R_2}{\log R_2 - \log R_1} \times (\log D_2 - \log D_1) \qquad (1)$$

An example should illustrate this test tubes with trypticase soy broth, containing different concentrations of streptomycin sulphate, were inoculated with 1×10^5 organisms of *Staphylococcus aureus*, type 81 per ml medium[4], and incubated for 18 h at 37° C The first tube showing no visible growth was that which contained 30 μg/ml The tube containing 20 μg/ml showed a percentage transmission reading of 91, while a tube containing 8 μg/ml gave a percentage transmission reading of 52 From equation (1) D_A, the dose causing absence of visible growth is found to be 23 34 μg/ml Though from this experiment it could be inferred that the organism is resistant to streptomycin, for which the limiting concentration is 20 μg/ml , repeated tests indicated a mean of 15 4 μg/ml

Using penicillin *G* potassium instead of streptomycin, a mean concentration of 70 5 units/ml was found to prevent visible growth, though in this specific experiment only 60 92 units/ml were needed This indicates that the organism is definitely resistant to penicillin, for which the limiting concentration is 10 units/ml

It has been pointed out that a 50 per cent endpoint reading has some advantages[1] In order to establish a 50 per cent end-point, several parallel inoculated trypticase soy broth tubes, without antibiotic, were set up After 18 h incubation, the growth is diluted with an equal volume of trypticase soy broth, the resulting tube contains 50 per cent of the bacterial number The percentage transmission reading ($R_{50\%}$) of this bacterial suspension is compared with the percentage transmission readings of the tubes containing antibiotic A tube with antibiotic will only by chance match the one containing 50 per cent of the bacterial number However, this dose, $D_{50\%}$, which would give 50 per cent growth inhibition, can be found by interpolation between two tubes, for which the doses, D_1 and D_2, and percentage transmission readings, R_1 and R_2, are known

$$\log D_{50\%} = \log D_1 + \frac{\log R_{50\%} - \log R_1}{\log R_2 - \log R_1} \times (\log D_2 - \log D_1) \qquad (2)$$

In an experiment, for example, the 50 per cent diluted control gave a percentage transmission reading ($R_{50\%}$) of 24 The tube containing 20 units/ml penicillin (D_1) gave a reading (R_1) of 12 8, the tube containing 60 units/ml (D_2) a reading (R_2) of 93 Using the equation (2), $D_{50\%}$ is found to be 28 33 units/ml In the same experiment 30 units/ml gave a percentage transmission reading of 25 Taking 20 units again as D_1 but 30 units as D_2, the result becomes 29 27 units/ml

Though it is preferable to interpolate for $D_{50\%}$, a good approximation can be obtained by extrapolation from two greater doses, D_1 and D_2, with readings R_1 and R_2

$$\log D_{50\%} = \log D_1 - \frac{\log R_1 - \log R_{50\%}}{\log R_2 - \log R_1} \times (\log D_2 - \log D_1) \qquad (3)$$

As stated here, $D_{55\%}$ for penicillin in one experiment was found by interpolation as 28 33 and 29 27 units/ml , respectively When extrapolating (equation 3) from $D_1 = 30$, $R_1 = 25$, $D_2 = 60$ and $R_2 = 93$, 29 36 units/ml is obtained

Combinations with different ratios of the two antibiotics were tried, and always run parallel to the controls and to the titrations of the single antibiotics If these two antibiotics were strictly additive, half the penicillin dose plus half the streptomycin dose should give the same effect as one full dose of either antibiotic In the above experiment visible growth was prevented by either 60 92 units penicillin/ml or 23 34 μg streptomycin/ml Consequently, 60 92 × 0 5 penicillin plus 23 34 × 0 5 streptomycin should yield the same effect as 60 92 units penicillin alone or 23 34 μg streptomycin alone In general, if simple addition prevails, this same effect should always be obtainable if the sum of the factors is one If smaller amounts than those expected are needed, synergism exists

Using penicillin and streptomycin in combination it was found, for example, that no visible growth occurred when the mixture contained 2·09 units/ml. penicillin and 4·18 μg/ml. streptomycin. This ratio (1 : 2) is of special interest, as it is the same as that of the maximum attainable concentrations in the blood, namely, 10 units penicillin/ml. and 20 μg streptomycin/ml. The above figures indicate that much less of either antibiotic is needed when they act in combination.

If there were only an additive effect, $\frac{60 \cdot 92 - 2 \cdot 09}{60 \cdot 92} \times 23 \cdot 34 = 22 \cdot 54$ μg/ml. streptomycin would be needed in order to complement the 2·09 units/ml. penicillin to the growth-preventing dose. It was found, however, that 4·18 μg/ml. streptomycin, instead of the expected 22·54 μg/ml. sufficed to complement the small dose of 2·09 units/ml. penicillin. The fraction: 22·54/4·18 = 5·39 is thus one measure of synergism.

Likewise, $\frac{23 \cdot 34 - 4 \cdot 18}{23 \cdot 34} \times 60 \cdot 92 = 50 \cdot 01$ units/ml. penicillin would be needed to complement the 4·18 μg/ml. streptomycin to the growth-preventing dose. The fraction: 50·01/2·09 = 23·93 becomes the other measure of synergism. Pooling both measures of synergism by taking their geometric mean, synergism is found to be: $\sqrt{5 \cdot 39 \times 23 \cdot 93} = 11 \cdot 36$.

Generally, let D_{A_1} be the dose of antibiotic 'one', causing a certain effect when acting alone, D_{A_2} the same for antibiotic 'two', $D_{A_1\text{ comb.}}$ and $D_{A_2\text{ comb.}}$ the effective doses of these antibiotics when acting in combination, then:

$$\sqrt{\frac{\frac{D_{A_1} - D_{A_1\text{ comb.}}}{D_{A_1}} \times D_{A_2}}{D_{A_2\text{ comb.}}} \times \frac{\frac{D_{A_2} - D_{A_2\text{ comb.}}}{D_{A_2}} \times D_{A_1}}{D_{A_1\text{ comb.}}}} \qquad (4)$$

or, simplifying:

$$\sqrt{\frac{(D_{A_1} - D_{A_1\text{ comb.}}) \times (D_{A_2} - D_{A_2\text{ comb.}})}{D_{A_1\text{ comb.}} \times D_{A_2\text{ comb.}}}} \qquad (4a)$$

is a measure of synergism.

If synergism obtains, the above expression (4*a*) is greater than unity.

The aforementioned experiments indicate that this penicillin-resistant *Staphylococcus* is rendered highly sensitive to penicillin by the presence of streptomycin; but also the amount of streptomycin needed is reduced to about one-third. Lower values for synergism are recorded when taking 50 per cent growth instead of the absence of visible growth as criterion. In the foregoing example, for example, 11·36 is reduced to 6·60.

The advantage of the combination over its two components acting singly becomes more pronounced with lengthening incubation time. As after 48 h incubation, in most instances, the tubes are either fully grown or show no visible growth, the results have to be based on these tubes from which growth is absent.

After 48 h, the mean growth-preventing dose is either 223 units/ml. penicillin, or 48 μg/ml. streptomycin.

The combination, which has the same effect, contains 4·5 units penicillin and 9·0 μg streptomycin; calculating synergism from formula (4*a*), 14·51 is obtained.

A GENERAL SYSTEM FOR THE AUTOMATIC SELECTION OF AUXOTROPHS FROM PROTOTROPHS AND VICE VERSA IN MICRO-ORGANISMS

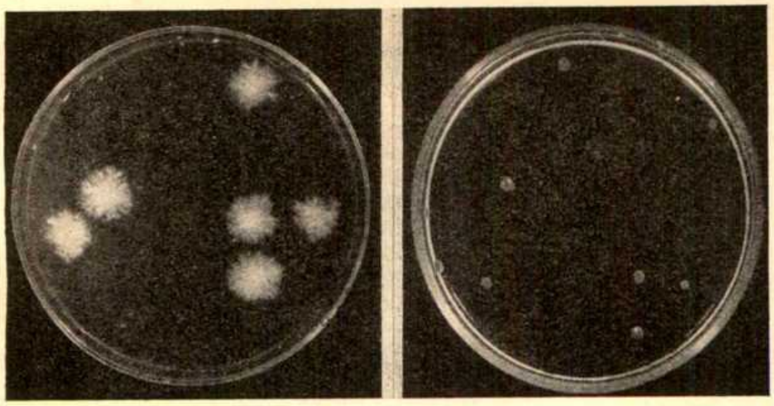
By D. APIRION

Department of Genetics, University of Glasgow

IN microbial genetics there have long been available techniques of high resolving power for the automatic selection of 'forward'-mutants, for example, in respect of resistance to drugs[1] and parasites[2], and of 'back'-mutants, for example, from auxotrophy to prototrophy[3,4]. The automation is based on establishing conditions such that cells of the parent strain —sensitive in the case of 'forward'-mutation to drug resistance, and auxotrophic in the case of 'back'-mutation to prototrophy—cannot grow while the 'forward'-mutants, or the 'back'-mutants, respectively, do grow.

It has been obvious for a long time that it would be very useful to be able to apply some such automation to selection in both directions in one and the same system. Most of the systems in which selection in both directions is possible have, so far, been only partially successful, mainly because of inadequate resolving power in either or both directions. To give a few examples: (1) Methods based on visual selection (for example, colour or morphology of the colony, enzymatic or other colour reaction, type of plaque, etc.) do select in both directions, but with low resolving power in both. (2) Methods based on drug resistance[1] or on host–parasite relations[5,6] or on reversion from auxotrophy[3,4] have a high resolving power but only in one direction. (3) Methods based on gradual enrichment[7-9] are not suitable for precise quantitative work. (4) Methods based on the fact that reversion from auxotrophy in respect of one growth factor sometimes involves mutation to auxotrophy in respect of another[10-13] are not sufficiently general.

The lack of a technique with high resolving power for the selection of mutants or recombinants in both directions in one system has been one of the main bottlenecks in genetic analysis at the intragenic level. Yet, the principles on which some such technique could have been based have been well known for a long time, and it is surprising that they have not been applied deliberately. There are examples in which these principles have been accidentally or incidentally used[14], and others[15,16] in which the results are likely to be interpretable on the basis of these principles. The principles are the following: consider a toxic analogue A' of a growth factor or metabolite A.



a b

Fig. 1. *a*, 5 × 10^6 conidia of a strain of *Aspergillus nidulans*, sensitive to fluoroacetate, plated on fluoroacetate medium (3 per cent, see text): six resistant colonies have developed. About 20 per cent of the resistants so obtained are auxotrophic, that is, unable to utilize acetate as sole source of carbon. *b*, 5 × 10^6 conidia of a strain resistant to fluoroacetate and unable to utilize acetate, plated on medium with acetate as sole source of carbon: eight prototrophic colonies have developed

Resistance to A' may—and often will—be based on failure to take up or further metabolize A', and therefore A. Resistant mutants of either type, that is, unable to take up or to utilize A, will be auxotrophic for one or more metabolites—for short, B—which the normal strain synthesizes from A. Thus, on a medium containing A' and B (or a substance which can replace B), 'forward'-mutants can be selected because they are resistant to A' (and by hypothesis, auxotrophic for B). 'Back'-mutants, capable of utilizing A and sensitive to A' can then be selected in the usual way, that is, by inoculating the auxotrophs in the absence of B but in the presence of A.

These very obvious considerations show how wide the field of search can be for systems in which selection in both directions at high resolving power may be possible. There is no need to stress how useful this possibility is for a variety of purposes: fine recombination analysis, specific mutagenesis at the intracistron level, etc. The search for suitable systems can start either from sensitive wild-type strains, selecting from them auxotrophs by virtue of their resistance to an analogue, or from auxotrophic strains, selecting those which are resistant to an analogue of a metabolite coming before the block which causes the auxotrophy. Clearly, as resistance can be achieved in a number of ways—of which the inability to take up or metabolize the toxic substance is only one—we should expect neither every resistant to a toxic substance to be auxotrophic in respect of a metabolite related to that toxic substance, nor every auxotroph to be resistant to a toxic substance related to the growth factor required by it.

The following is an example of a system of the first kind. It was based on selection of 'forward'-mutants by means of their resistance to an analogue (fluoroacetic acid). Some of these resistant mutants are auxotrophic, and more precisely unable to utilize acetate as the only source of carbon. 'Back'-mutants of these auxotrophic resistant mutants can be selected by plating them on a medium with acetate as the only source of carbon.

Most *Aspergillus nidulans* strains can grow on acetate as the only source of carbon. For the purpose of the present work a medium of the following constitution (per 1,000 ml.) was used: ammonium acetate, 12 gm.; sodium chloride, 2 gm.; magnesium sulphate (7 H_2O), 0·5 gm.; potassium dihydrogen phosphate, 3 gm.; ferrous and zinc sulphate, traces; agar, 12 gm.; pH adjusted to 6·1 by ammonium hydroxide or hydrochloric acid.

Fluoroacetate at high concentration prevents the growth of most *A. nidulans* strains. The fluoroacetate medium used for obtaining resistant mutants was as follows (per 1,000 ml.): glucose, 5 gm.; sodium nitrate, 4 gm.; potassium chloride, 1 gm.; magnesium sulphate (7 H_2O), 0·5 gm.; potassium dihydrogen-phosphate, 3 gm.; ferrous and zinc sulphate, traces; fluoroacetic acid (technical), 30 gm.; agar, 15 gm.; pH adjusted to 6·1 by concentrated ammonium hydroxide. On this medium sensitive strains do not grow, while resistant strains grow well (Fig. 1).

To select resistant mutants, suspensions of up to about 10^8 conidia/ml. from fluoroacetate-sensitive strains capable of utilizing acetate as the only source of carbon were spread in volumes of 0·1–0·2 ml. on the surface of the fluoroacetate agar medium (25 ml./dish). When mutagenic treatment was used, for example, nitrous acid[17], part of the suspension was treated before plating. After a few hours incubation a further thin layer of the same fluoroacetate medium (3–5 ml./dish) was poured on top. Resistant colonies began to appear 3–4 days later, and by the sixth or seventh day they were isolated on a complex medium with glucose as the main carbon source. These resistant mutants were then tested for their ability to grow on acetate medium. Of the 30 resistant mutants obtained after nitrous acid treatment (Table 1) 6 were also auxotrophic, that is, not able to grow on acetate as only source of carbon (Fig. 1), and required an alternative source, for example, succinate or glucose.

Back-mutants from these resistant auxotrophs were selected by plating the conidia on medium with acetate as the only carbon source. Table 2 shows, as an example, the results of plating on such medium three different suspensions of untreated conidia from one

Table 1. SELECTION OF 'FORWARD'-MUTANTS RESISTANT TO FLUOROACETIC ACID

Exp.	Treatment	Conidia per dish (× 10^3)	Total conidia plated (× 10^3)	Resistant mutants: No.	Resistant mutants: per 10^6 plated conidia

Table 2 SELECTION OF SPONTANEOUS 'BACK'-MUTANTS ABLE TO UTILIZE ACETATE AS SOLE CARBON SOURCE FROM ONE 'FORWARD'-MUTANT (*f* 10) RESISTANT TO FLUOROACETIC ACID AND UNABLE TO UTILIZE ACETATE

Exp	Conidia per dish (× 10^6)	Total conidia plated (× 10^6)	Back mutants No	Back mutants per 10^6 plated conidia
I	45	135	19	0 14
II	120	240	112	0 47
III	60	180	37	0 20
			168	

resistant auxotrophic strain (*f* 10) Of the 168 back-mutants from this strain obtained in this way, 24 were tested on fluoroacetic acid medium; all were sensitive

As expected, not all resistant auxotrophs back-mutate, and those which do so may back-mutate both in respect of the auxotrophy and of the resistance, or only in respect of the auxotrophy So far, 29 resistant auxotrophs of independent origin have been tested for back-mutation (minimum per strain 2 × 10^8 conidia) Of these, six did back-mutate, and one of them back-mutated in respect of the auxotrophy but remained resistant to fluoroacetic acid

This attempt in one specific case shows that the general principles mentioned at the beginning are valid and that forward and back selection, based on resistance determined by auxotrophy, is possible with high resolving power in both directions

I thank Prof G Pontecorvo for guidance, Mr E Forbes for advice and Dr O H Siddiqi for a discussion which led to this work

CATABOLISM OF DOUBLY LABELLED THYROXINE *IN VIVO*

By Dr L. G PLASKETT

Department of Biochemistry, University of Edinburgh

THERE is some evidence that the peripheral breakdown of thyroxine involves a reaction sequence in which the release of inorganic iodide from the 3′ . 5′ positions precedes similar release from the 3 . 5 positions This was first clearly indicated in the work of Roche, Michel and Tata[1], in which the rate of excretion in the rat of the iodine-131 of $[3'\ 5'{}^{131}\mathrm{I}_2]$ thyroxine was found to exceed that of the iodine-131 of $[3\ 5{}^{131}\mathrm{I}_2]$ thyroxine Clearly, metabolic separation of the iodine of the two rings had occurred, compatible either with diphenylether bond cleavage or with more rapid de-iodination of the thyroxine β ring than of the α ring These conclusions from experiments *in vivo* have received support from experiments *in vitro* with rat liver extracts in which a metabolite of thyroxine was identified which contained the iodine atoms from the thyroxine α ring only[2,3] The iodine from the β ring appeared as inorganic iodide The properties of this metabolite suggested that it may still contain the de-iodinated thyroxine β ring, which could be hydrolysed off by treatment with cold weak alkali, yielding diiodotyrosine This metabolite may be a hydroxylated derivative of 3 5 diiodothyronine

The special interest of this unknown metabolite arises from the long-standing hypothesis that partial de-iodination may be necessary in order to generate an active form of the thyroid hormone from thyroxine[4–7] Studies with thyroxine analogues have shown that substituted thyronines which contain no iodine (or bromine) on the α ring are physiologically almost inactive[8], whereas compounds devoid of iodine on the β ring are often active if the iodine is replaced (though not necessarily in the 3′ 5′ positions) by other substituents such as methyl or isopropyl[9] Therefore, if an active form of the thyroid hormone is generated by partial de-iodination of thyroxine, the de-iodination must presumably occur at positions 3′ or 5′, or at both The preferential de-iodination of the β ring is therefore a subject worthy of the closest possible scrutiny, and any metabolite from which some or all of the iodine of the β ring has been removed may be identical with or closely related metabolically to the active form of the hormone

The finding of partial de-iodination *in vitro*[2,3] conflicts with a report that thyronine is the product of the de-iodination of thyroxine in rat liver slices[10], and it has been commented that this conflict cannot be resolved on present evidence[11] The conflict probably arises, however, because of the different nature of the two *in vitro* systems which were used Liver slices, which fail to de-iodinate thyroxine at a rate comparable with that observed in liver extracts, produce none of the unknown metabolite which contains the α-ring iodine atoms only and which liver extracts produce in more than 50 per cent yield[12] Similarly, the findings of Yamasaki and Slingerland[13] that liver tissue catalyses the complete de-iodination of thyroxine were obtained using homogenates instead of extracts, and it is known that these two types of preparation differ markedly in their de-iodinating properties There is therefore no conflict of experimental findings, but the publication of two sets of data, one relating to an *in vitro* system which preferentially de-iodinates the thyroxine β ring, and the other which attacks both rings indiscriminately, calls for a re-examination of the early work on the excretion-rate of iodine-131 from thyroxine labelled on either ring Such re-examination has been undertaken by me in an attempt to confirm or refute the findings of Roche, Michel and Tata[1] The experiments of the French workers have been repeated with three main differences These were (1) the use of euthyroid experimental animals, (2) the use of doubly labelled $[3\ 5'^{131}I_2,\ 3'\ 5'^{124}I_2]$ thyroxine instead of the separate use of $[3\ 5^{131}I_2]$ thyroxine and $[3'\ 5'^{131}I_2]$ thyroxine, (3) the extension of the work to investigations in the guinea pig as well as the rat.

In spite of the obvious technical advantages to be gained by using thyroidectomized animals for de-iodination studies, it was decided to use euthyroid animals because thyroidectomy and hypothyroidism are now known to influence the activity of the peripheral de-iodinases[14,15]

The use of doubly-labelled thyroxine containing a different radioactive isotope of iodine on the two rings eliminated difficulties arising from the individual variations of laboratory animals the metabolic fate of both rings could thus be determined in the same animal The doubly-labelled material was synthesized by producing [^{131}I] 3 . 5-diiodothyronine as described elsewhere[3] and iodinating this with iodine containing iodine-124 It is known that in this synthesis the iodine which is introduced during the first and second iodination stages is confined specifically to the α and β rings respectively[16] The extent of labelling on the two rings was determined by the diazo-coupling method[17]

Into each of the animals (male Wistar albino rats and male guinea pigs) 2 μc of the doubly labelled hormone (4 μgm) was injected intraperitoneally Urine and fæces were collected for six days after the injection Each urine sample (collected over successive periods of 24 hr) was counted in a type *M*6 (20th Century Electronics) β counter immediately after collection and stored for exactly twelve days before being counted a second time The radioactivity of the different urine samples decayed at different rates depending on their content of iodine-131 (half-life 8 04 days) and iodine-124 (half-life 4 24 days[18]), and by measuring the rate of decay the proportion of iodine-131 and of iodine-124 present in each urine specimen could be calculated This was done as follows Where the count-rate of the urine specimen after collection is known, it is possible to calculate a figure, x, for the expected count-rate after 12 days assuming the original activity to have been entirely iodine-131 Similarly, a figure, y, can be obtained based on the assumption that the original activity was entirely iodine-124 If the observed count-rate after 12 days is z, then the percentage of iodine-124 present on the day of collection was

$$\frac{x - z}{x - y} \times 100$$

This relationship was shown to hold for the decay of control mixtures of iodine-124 and iodine-131 of known original composition It was found possible in this way to detect the presence of only 1 per cent of iodine-124 in a mixture of the two isotopes

Figures thus obtained for the isotope composition of the radioactive urines applied to the day of collection only A mixture of iodine-124 and iodine-131 continuously changes its composition towards a heavier preponderance of iodine-131 The isotope composition of the urine samples was therefore expressed as the composition which the samples would have had on the day of injection, when the administered thyroxine contained 34·6 per cent iodine-124, all located on the β ring, and 65 4 per cent iodine-131, all located on the α ring

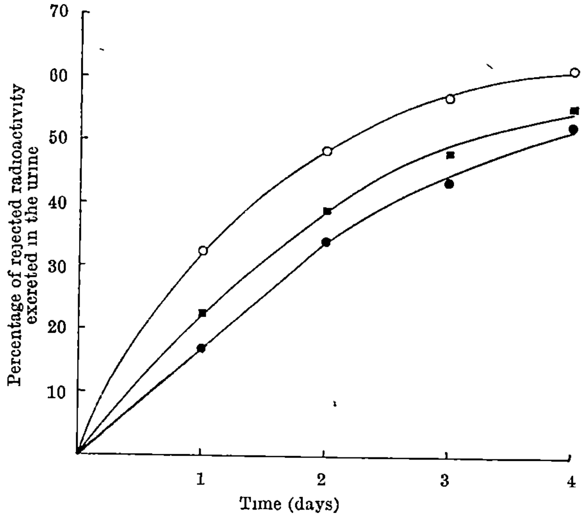

Fig 1 Urinary excretion of the iodine-124 (open circles), iodine-131 (filled circles) and total radioactivity (filled squares) of doubly labelled thyroxine in the rat as a function of time

The results showed that during the first 24 hr after injection of thyroxine the urine contained more than 50 per cent of its radioactivity in the form of iodine-124 It contained 33 per cent of the total iodine-124 administered and only 17 per cent of the administered iodine-131 There was no significant difference between the rat and the guinea pig in this respect During the second 24-hr period the two isotopes were excreted in the same ratio in which they were administered in the labelled thyroxine, the urines containing 34 per cent iodine-124 Thereafter the preponderance of iodine-131 increased During the fourth 24-hr period after injection the rats excreted urine containing only 27 per cent of its radioactivity as iodine-124 This was the last measurement which could be obtained in the rats on account of the low levels of radioactivity During the fifth 24-hr period the guinea pigs excreted urine containing 22 per cent iodine-124

Fig 1 illustrates the progress of the urinary excretion of the two isotopes with time

The work reported here thus confirms the findings of Roche, Michel and Tata[1] *In vivo* excretion of the iodine from the β ring, and therefore presumably de-iodination from that ring, is shown to occur more rapidly than from the α ring It follows that metabolic intermediates containing only the iodine from the α ring are to be expected in *in vitro* systems which truly reflect the *in vivo* happenings It cannot be denied, however, that there may be several de-iodinating pathways in the intact organism If this is the case then a pathway leading to the formation of thyronine and one generating partially de-iodinated metabolites may co-exist in the same tissue It is difficult to envisage what could be the function of the system which catalyses total de-iodination unless it be to remove excess thyroxine This hypothesis would presuppose either that thyroxine itself is the active form of the hormone or that the active form is generated by another metabolic pathway, since thyronine has no activity On the other hand, partial de-iodination holds the possibility that an active form might be produced, especially if the removed iodine is replaced by other substituents, such as hydroxyl groups The finding that 3′-hydroxy 3 5 diiodothyronine is physiologically inactive[19] does not necessarily conflict with this view because this substance is labile and may never reach the target organs intact The active form of the hormone may well be a labile compound which is formed *in situ* within the cell and which shows no physiological activity when presented to tissue extracellularly

Note Since the completion of the experimental work which is described in this communication several apparently conflicting reports have appeared on the subject of thyroid hormone catabolism Thus, further details of the kidney system which catalyses the monode-iodination of thyroxine to triiodothyronine have been published[20] By contrast with this a report has appeared which presents good evidence that the pathway from thyroxine to thyronine passes through intermediate stages of de-iodination in which the iodine atoms of the α ring are the first to be removed[21] This finding cannot be readily reconciled either with my work already referred to[2,3] or with that of Nunez and Jacquemin[22], who identified tritium-labelled iodotyrosines as metabolites of tritium-labelled thyroxine

These and other tracer investigations have brought the subject of thyroxine catabolism to the point where a very large number of the theoretically probable pathways can be shown actually to exist in *in vitro* systems In this situation, studies *in vivo* with thyroxine specifically labelled in different positions with more than one isotope may prove to be particularly valuable

KINETICS AND OXYGEN REQUIREMENTS OF A LIGHT-INDUCED ELECTRON SPIN RESONANCE SIGNAL FROM WHOLE SPINACH CHLOROPLASTS

By W H STOREY, C. M MONITA and D. G CADENA, jun

Southwest Research Institute, San Antonio, Texas

ELECTRON spin resonance observations of suspensions of whole spinach chloroplasts performed in this laboratory have certain features which should contribute to a characterization of the structures giving rise to the signals The signals bear similarities to signals observed in other laboratories from spinach chloroplasts[1,2], from *Chlorella*[3], from both whole and fragmented red algae, strain *TX*27 (ref 4) and from crystalline chlorophylls[5,6] This article will be concerned chiefly with rise and decay kinetics of the rapidly decaying light-induced signal and with the dependence of its appearance on oxygen

Whole chloroplasts were prepared immediately following gathering of the leaves of spinach (*Spinacea oleracea*) grown by sand culture in this laboratory The preparation procedure was a modification of methods described in the literature[7,8] Sample temperature was held below 4° C and sample illuminance was maintained at a low level whenever possible A Waring blender operated for three 10-sec periods was used for the initial extraction The aqueous extraction medium was a 0 04 M sucrose solution containing 0 01 M potassium chloride and buffered with 0 05 M disodium hydrogen phosphate and potassium dihydrogen phosphate, yielding a *p*H of 6 8 After filtering the homogenate through cheesecloth, purification was accomplished by centrifugation first at 200*g* for 1 min, followed by centrifugation of the supernatant at 1,400*g* for 7 min The chloroplasts were re-suspended without washing in 5 ml of the same buffered solution used for extraction Microscopic examination showed the absence of large contaminating particles, but the absence of such small particles as grana and mitochondria was not determined The chloroplasts themselves appeared intact The concentration of chlorophyll *a* + *b* in undiluted preparations measured 1 7 mg/ml by a method described by Arnon[9] In measurements of Hill activity, 20 μmoles/ml chlorophyll/h of 2,3′,6-trichloroindophenol sodium salt (Eastman practical grade) were reduced, following a method described by Jagendorf[7] This consistently low value of Hill activity remains unexplained

Samples for electron spin resonance observation measured 8 × 23 × 0 37 mm and were contained in quartz 'Varian' electron spin resonance instrumentation operating at a modulation frequency of 100 kc/sec was used with the single modification that the slotted cover furnished for the cavity window was replaced by fifty 3-mil gold-plated tungsten wires, giving a transmission for light into the cavity of 83 per cent with negligible deterioration in cavity *Q* A Bausch and Lomb grating monochromator with incandescent light source, giving an output ranging from 6 × 10^{14} (550 mμ) to 1 4 × 10^{15} (730 mμ) photons cm^{-2} sec^{-1} at a band-width of

13 2 mμ, provided the illumination Sample temperatures were 25° ± 2° C

Two electron spin resonance signals must be distinguished There is a signal with no apparent hyperfine splitting (g = 2 0030 ± 0 0006 and line width = 7·0 gauss), so short-lived in the dark that it is obviously light-induced (*LS*, Fig 1*a*) There is a signal with apparent hyperfine splitting so long-lived in the dark (several tens of minutes) that its light dependence is not so obvious (*DS*, Fig 1*b*) The dark signal has not appeared with sufficient resolution to enable us to confirm Commoner's assignment of five lines[1] The similarity in appearance between our signals and those from crystalline chlorophyll *a* + *b* exposed to water vapour[6] is noteworthy. The action spectrum for effecting the light-induced signal has a single peak at 716 ± 5 mμ, with values of zero for the range 550–650 mμ and again above 760 mμ An action spectrum for a chloroplast paste reported in the literature is similar to that reported here at the long wave-length end, but action was reported from 500 to 650 mμ (ref 2)

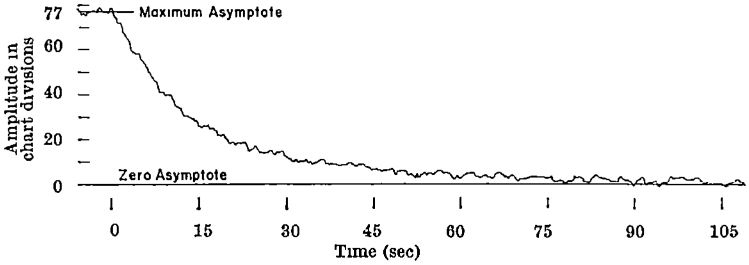

Fig 2. Decay curve for a suspension of whole spinach chloroplasts

Discussion of oxygen dependence requires that a process which inhibits the ability of the sample to give the light-induced signal be distinguished from the process by which the light-induced signal is given This inhibiting process is more rapid at 675 mμ than at 715 mμ, and it is more rapid for a sample examined within the first hour following preparation than for a sample aged overnight at 0° C with exposure to air Illumination of a sample exposed to air does not result in inhibition, but illumination with tank nitrogen bubbling through the sample does eliminate the light-induced signal Bubbling tank nitrogen through a dark air-equilibrated sample can result in a 13 per cent reduction in light-induced signal intensity, but not complete inhibition Following inhibition, with no light-induced signal observable in the range 550–760 mμ, the ability of the sample to give the light-induced signal is renewed by bubbling through it either air or tank oxygen Neither tank nitrogen nor tank carbon dioxide is effective Therefore, in order to effect the light-induced signal by 715 mμ illumination, the prior addition of oxygen to the suspension has been found a sufficient condition Since no Hill oxidants were added, there is a probable consumption of oxygen at 675 mμ through the Mehler reaction[10]. Furthermore, the dimensions of the sample cell are such that the sample can become anaerobic readily The dark signal apparently does not need oxygen

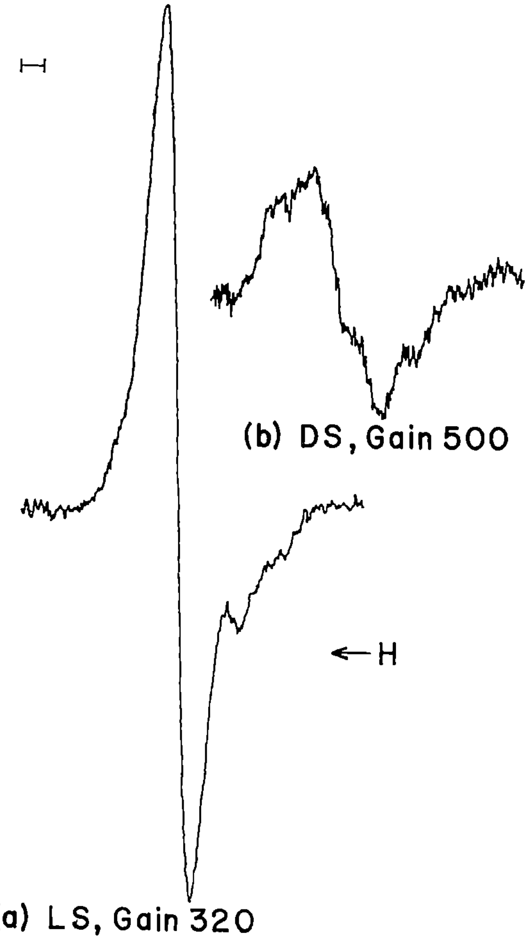

Fig 1 *a*, Light-induced (720 mμ), and *b*, dark electron spin resonance signals from whole spinach chloroplasts

Figs 2 and 3 show decay and rise curves obtained by adjusting the polarizing magnetic field H_0 to a value causing the light-induced signal to peak, and operating a shutter interposed in the light beam Analysis of the decay curves gives both a slow and a fast exponential component with a fast/slow amplitude ratio of 3/1 at zero time The decay half-times depend on the exposure of the sample to oxygen and to light Bubbling oxygen rather than air through a sample increases the decay half-times by at least one order of magnitude Exposure of the sample to 715 mμ light decreases the dark decay half-times, probably through oxygen consumption During the observation of four sets of rise and decay curves over a period of 18 min using a single air-equilibrated sample, the fast/slow decay half-times in seconds were as follows 7 4/31, 6 5/29, 5 3/27 and 4 5/25

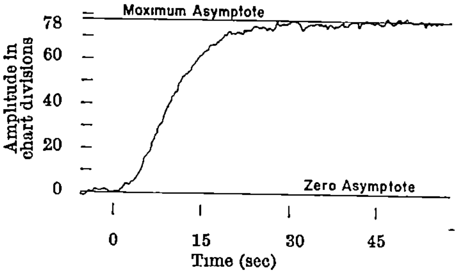

Fig 3 Rise curve at 720 mμ for a suspension of whole spinach chloroplasts

Figs 2 and 3 show the first set of decay and rise curves

During rise, the curves reached maximum slope only after several seconds of exposure to 720 mμ light In general, the slope at zero time is difficult to determine, but during its first 6 sec the rise curve shown in Fig 3 is parabolic Prior to obtaining this curve, the sample had been dark for 8 min Later curves taken after holding the sample in darkness for only 2–3 min gave briefer induction periods, as if a long-lived intermediate with no observable unpaired spin were present at zero time A reaction scheme fitting the rise curves precisely has not yet been obtained The necessity for including oxygen in such a reaction scheme cannot be asserted, since there remains the possibility that its only function in making the light-dependent signal observable is to alter the structure of some substance that is chiefly responsible for the rapid decay of the light-induced signal

AEDES AEGYPTI (L.) AND *AEDES MASCARENSIS* MACGREGOR IN MAURITIUS: A CASE OF GENE SURVIVAL FOLLOWING SPECIES ERADICATION?

By G. A. H. McCLELLAND*
London School of Hygiene and Tropical Medicine, W.C.1
AND
RAYMOND MAMET
Medical and Health Department, Mauritius

THE successful hybridization of the mosquito *Aedes aegypti* (L) with *Aedes simpsoni* (Theo)[1], using a method of force-mating[2], has been followed by attempts using other species with genitalia closely resembling *A aegypti* and *A simpsoni* Among these, matings of *Aedes mascarensis* MacGregor and *A aegypti* were fully successful in both directions and yielded vigorous fertile hybrids

The latter F_1 hybrids resembled *A aegypti* except for partial expression of the strikingly pale mesonotal scaling of *A mascarensis* (Fig 1*A*, *C*, *D*) The F_2 and subsequent hybrids showed independent segregation of at least four of the characters used in distinguishing the adults of *A. mascarensis* from *A aegypti* Two of these (absence of femoral 'knee' spots and broadly crescentic anterolateral mesonotal spots) have been separately maintained on a background otherwise like *A aegypti* for up to five further generations The question immediately raised is that of natural hybridization

A mascarensis was first described in 1923 [3], and is known only from the island of Mauritius in the south Indian Ocean where *A aegypti* also occurred until its reported eradication in 1950 [4] Although the larva and male genitalia resemble those of *A aegypti*, the adults of the two species can be separated on nine distinct morphological characters of the head and thorax The genetic control of four of these characters at independent loci, as here reported, indicates that *A mascarensis* is not merely a polymorphic form of *A aegypti* What is known of its biology suggests that it is a species of distinct habits and distribution

A aegypti in Mauritius was restricted to coastal urban areas while *A mascarensis* is largely sylvan, larvæ of the two were never found in the same breeding place[3,5] *Aedes albopictus* Skuse, the commonest species in Mauritius and known competitor of *A aegypti* in Malaya and elsewhere[6,7], occurred in all the habitats of *A mascarensis*, larvæ of the two species often sharing the same tree-hole breeding place[3,5] *A albopictus* was moreover present in the semi-domestic habitat of the urban fringe[5] where it possibly interfered with the outward spread of *A aegypti* and contributed to the virtual isolation of that species from *A mascarensis*

The possibility of hybridization between *A aegypti* and *A mascarensis* in nature was first suggested as the possible origin of another Mauritian 'species' *Aedes vinsoni* Mattingly[8], combining superficially the pale mesonotum of *A mascarensis* with the pale abdomen of *A aegypti* var *queenslandensis*[8] In the present laboratory work, F_1 and F_2 hybrids with the palest variety *queenslandensis* from Saudi Arabia showed no approach to *A vinsoni* Furthermore, the type specimen of *A vinsoni* in the British Museum (Natural History) shows a clearer affinity with *A albopictus* than with either *A mascarensis* or *A aegypti* The recent capture on the island of a female mosquito intermediate between *A vinsoni* and *A albopictus* emphasizes this point Mattingly[9], who describes it as a second specimen of *A vinsoni*, again raises the possibility of hybridization There seems, however, no reason why '*A vinsoni*' should not be a rare variety of *A albopictus* genetically analagous to var *queenslandensis* of *A aegypti*

In 1961, out of a total of 120 adult *A mascarensis*, both wild-caught and reared in London from eggs, 45 lacked the mesonotal pale scaling so characteristic of the species (Fig. 1*B*) In all other respects these resembled the remainder, which agreed with earlier descriptions[3,5,10] In 1962, further adults reared in London, from eggs laid in Mauritius by wild-caught females, revealed three other characters of *A aegypti* occurring independently At the most only 4 males and 11 females out of 38 of each were true to type,

---

* Present address Department of Biology, University of Notre Dame, Indiana, U S A

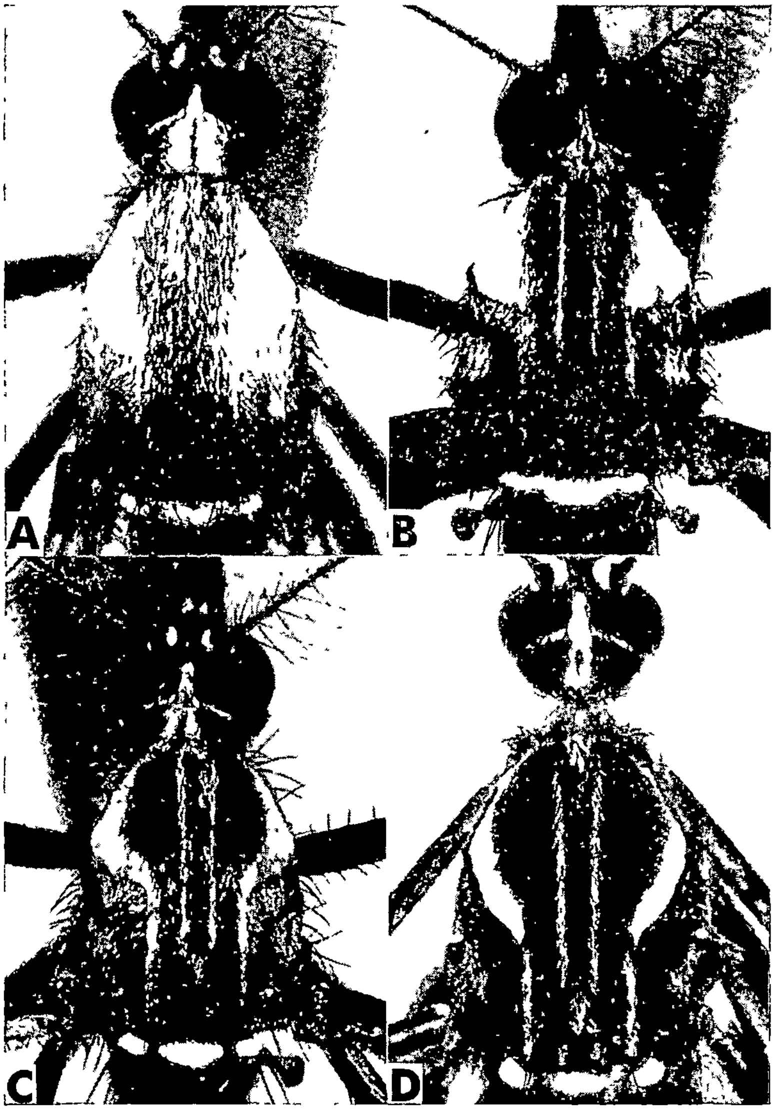

Fig 1 Dorsal aspect of the head and thorax of anæsthetized female mosquitoes *A*, typical *Aedes mascarensis* MacGregor reared from eggs laid by wild-caught female (1961), *B*, atypical form from same egg batch as *A*, *C*, F_1 laboratory hybrid of a typical *A mascarensis* male with a female of *Aedes aegypti*, *D*, typical *A aegypti*

and 3 females superficially resembled *A aegypti* Had such intermediate forms occurred three or four decades ago it is unlikely that MacGregor[3, 5] would have overlooked them

How can the presence of these '*aegypti* genes' in the population of *A mascarensis* be explained? It is scarcely plausible that so many dominant mutations, each coinciding with a character possessed by *A aegypti*, should have arisen to co-exist with high frequencies Alternatively, these genes might be relicts in a case of incipient speciation The recently eradicated population of *A aegypti* in Mauritius was probably one or both of the paler urban forms[6,8] which spread round the world with man but nowhere, outside the African mainland, evolved truly feral, let alone sylvan populations The possibility that not only did such speciation happen in Mauritius in less than a thousand years[11], but also that in the presence of *A albopictus* there arose a form as distinct from *A aegypti* as *A mascarensis*, would be remarkably rapid evolution If it had, it is even more surprising that the eradication of the initial form should seem to lead to a reversal of the process A third possibility will now be suggested

In the colour of its abdomen *A mascarensis* resembles not the type form or variety *queenslandensis* but the feral sub-species *formusus* of *A aegypti*[6] and other closely related species on the African mainland It seems possible that *A mascarensis* developed in isolation from an ancient population of *A aegypti* or some common ancestral form The reverse, that *A aegypti* and perhaps other group *A Stegomyia* in Africa might have arisen from something like *A mascarensis*, has been suggested[6] In either case, later re-introductions of man-adapted urban forms of *A aegypti* into Mauritius would have been virtually isolated from sylvan *A mascarensis* until recent urban expansion and perhaps the effect of control measures may have stimulated some overlap in their distribution Under these conditions some hybridization and consequent gene exchange is a distinct possibility

In the light of this point of view, it appears that although *A aegypti* has now been eradicated from the island, more than ten years of surveillance having failed to reveal it, its genes apparently still survive in *A mascarensis* at frequencies which may be increasing Although *A mascarensis* has in no way changed its habits since the eradication of *A. aegypti* it may now possess new genetic potential Selective forces might slowly bring about a recrudescence in the island of an urban *Stegomyia* not necessarily wholly like *A aegypti*, but capable of feral coexistence with *A albopictus* and probably less amenable to control Relative to *A aegypti* elsewhere the situation in Mauritius is almost certainly unique, but it suggests an additional type of hazard that may be met in insect control operations

A full account of the present work on hybridization in *Stegomyia* is being prepared for separate publication This work formed part of a research programme supported by the Colonial Development and Welfare Fund We thank Mr P F Mattingly for allowing us to read his paper in manuscript

SOLAR FLARE EFFECTS ON LIVING ORGANISMS CONFINED IN MAGNETIC FIELDS

By W C. LEVENGOOD

Institute of Science and Technology, University of Michigan, Ann Arbor, Michigan

AND

M P. SHINKLE

Indiana University School of Medicine, Indianapolis, Indiana

SOLAR phenomena are known to influence living organisms on Earth The investigations of A E Douglass, for example, indicated a relationship between sun-spot numbers and the growth patterns in tree rings Solar flare activity, which is at present recorded on a diurnal basis, has received less consideration in terms of possible biological effects, even though active flares are known to be rather prolific sources of energetic particles Most evidence of the terrestrial effects of solar flares has been obtained through investigations of radio communication fade-out and magnetic field variations during periods of intense flare activity

It will be shown here that secondary effects from solar flares influence progeny variations in the fruit fly, *Drosophila melanogaster*, when these organisms are subjected to a magnetic field The present investigation came about as the result of earlier work[1], which disclosed that *Drosophila* productivity was affected by various environmental conditions A correlation was shown between barometric pressure recorded during the initial mating period and the resulting progeny Growth in an electric field reduced this correlation and produced a 35 per cent greater yield compared with control cultures In a later discussion[2], this electric field effect was attributed to variations in air-ion densities

The deflexion of charged particles by magnetic fields provides a possible tool for changing ionic concentrations within limited spatial regions It was postulated that organisms grown within a magnetic field would conceivably be exposed to a different environment of energetic particles than in control cultures Experimental work was initiated, and an influence of the magnetic field was indicated It was during a critical analysis of these experimental results that the possibility of solar flare influences was discovered

Drosophila were exposed to magnetic fields by placing culture bottles on the poles of permanent magnets, as shown in Fig 1 (Magnets were magnetizers (type *A*-1007) made by Indiana Steel Products, Valparaiso, Indiana) The field strength at the centre of each 4 5 cm square pole was about 1,000 gauss on the face and 350 gauss 1-in above (the separation between poles was approximately 8 cm from centre to centre) The magnets were set in one of four geomagnetic orientations (designated for each set of data), and this orientation was maintained throughout an entire series of generation matings For example, east (N)–west (S) gives the geomagnetic direction and the letters in parenthesis the direction of the poles of the magnet , in this example the N pole is oriented east and S pole west The culture bottles were about 5 cm in diameter and 11 5 cm high and covered the pole pieces Each bottle was held in position on the magnet with tape, and media was placed in the bottom to a depth of about 2 5 cm Room temperature was held at 22° ± 2° C

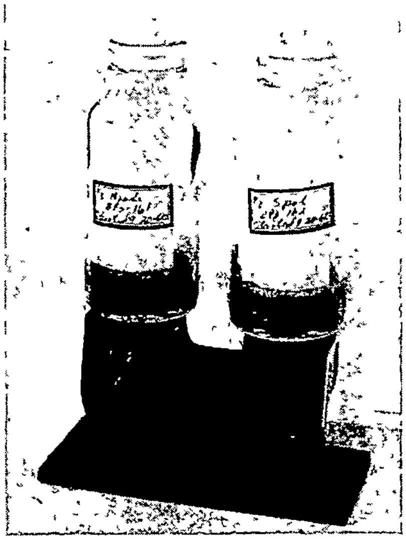

Fig 1 Test magnet with culture bottles in position

Culture bottles designated as (N) and (S) pole were compared as pairs in each generation, and after a given generation series was started in the F_1, repeated filial generation crosses were made Three adult pairs removed from the preceding F generation were left 10 days in the bottles, then removed before new flies emerged Several countings were made over an 8-day interval starting with the day the new generation flies were seen The cultures were left in the magnetic field except during the brief periods of counting Cultures designated as 'controls' were also simultaneously grown out of the magnetic field and all cultures, including the controls, were initiated as well as removed and counted on the same dates Flies exposed to the field were normal or wild-type (Flies were obtained from the Carolina Biological Supply Co , Elon College, N C regular banana cultures were used with 0 1 per cent mould inhibitor)

These data were statistically analysed with a previously used[1] correlation coefficient (r) for ungrouped data given as .

$$r = \frac{n\Sigma F_t \quad M - (\Sigma F_t)\ (\Sigma M)}{[n\Sigma F_t^2 - (\Sigma F_t)^2]^{1/2}\,[n\Sigma M^2 - (\Sigma M^2)]^{1/2}} \qquad (1)$$

where F_t represents the total number of flies per filial generation, n the number of generations and M the independent parameter being examined, such as barometric pressure (P), solar flare activity (S_F) or a factor involving both (to be discussed later) The results are considered significant at the 95 per cent confidence-level if

$$r > \pm 1\ 96/(n-1)^{1/2} \qquad (2)$$

Barometric pressures were recorded in the laboratory with a mercury barometer The solar flare index was obtained from preliminary and summary reports of solar activity issued by the High Altitude Observatory, Boulder, Colorado (Solar activity summaries prepared by D E Trotter and W O Roberts, High Altitude Observatory of the University of Colorado for the International Geophysical Corporation) The barometric pressure P and solar flare S_F values were averaged over a 72-hr period covering the day before, the day of and the day after the initial mating of each generation The use of this specific 72-hr period is based on two factors, one is the previous findings[1], which showed that this time-period produced the highest degrees of correlation with barometric pressure, and the second factor is the unsuccessful attempts (low correlations) in the present study when using solar flare activity values covering other time intervals within the generation periods

An analysis (using equation 1) of the progeny yields obtained from a number of generations grown in the magnetic field disclosed a low correlation of progeny with barometric pressure, with r values considerably below the level of significance given by equation (2) This finding was not in accord with the results from control cultures (grown out of the field), which showed positive, significant correlations between progeny and barometric pressure This reduced correlation between progeny grown in the magnetic field and barometric pressure indicated that the magnetic field altered the environmental conditions Solar effects were considered as possible factors in changing the environment within the magnetic field No obvious correlations were found between daily sun-spot numbers and progeny Diurnal solar flare activity values did, however, show interesting possibilities

Reported flare activity values may show day to day changes of several orders of magnitude, therefore the logarithm of solar activity was used for correlation purposes This logarithmic treatment of flare activity reduced the marked fluctuations to reasonable values for comparing with progeny and barometric pressure parameters, both of which generally disclose variations of less than one order of magnitude This solar activity parameter is

$$M = \log(S_F + 1) \qquad (3)$$

where ($S_F + 1$) allows, on a logarithmic scale, a data point for an occasional sequence of zero values for S_F over the 72-hr mating period

Progeny yields from a nine generation series raised in the magnetic field are shown in Fig 2 and compared with the solar flare activity The method of plotting the results in Fig 2 was chosen simply as a convenient way to illustrate the corresponding maxima and minima in the progeny and solar flare curves The environmental parameters (solar flare activity and barometric pressure) and progeny yields are time independent events (that is, no systematic variations with time), therefore, in the statistics used (equations 1 and 2), only the interdependence between the environmental parameters and progeny yields are considered The progeny curves in Fig 2 appear to vary inversely with solar flare activity (equation 3) Although both the N and S progeny curves in Fig 2 show similar variations, the S pole progeny variations disclose a slightly higher degree of inverse fluctuation with solar flare activity , the correlation coefficient for the N pole data in Fig 2 is $r_N = -0\ 78$, and the S pole $r_S = -0\ 82$, both significant at the 95 per cent level of confidence

Each generation series grown in the magnetic field was continued until the flies in a culture on one or both poles either died out or gave very few progeny, and termination (zero progeny) often occurred when flare activity was high, as happened, for example, in the series shown in Fig 2 The F_9 mating period in Fig 2 was on April 26, 1961, and the preliminary report stated that the flare activity on this date "caused a short wave radio disturbance"

In one series of tests, two magnets were oriented east (S) – west (N) and each new generation series was initiated at the same time on both magnets The progeny yields from the set of S pole cultures are shown in the middle set of curves in Fig 3 for a nine-generation sequence The S pole curves disclose similar fluctuations whereas the deviations in the N pole data (bottom curves in Fig 3) are more pronounced Also given in Fig 3 (upper curve) is the solar flare activity for the same generation periods Again it appears that increases in solar flare activity correspond with decreasing trends in progeny yields This effect may be especially noted in the S_2 curve in Fig 3, where the progeny variations follow the fluctuations in the solar curve more closely

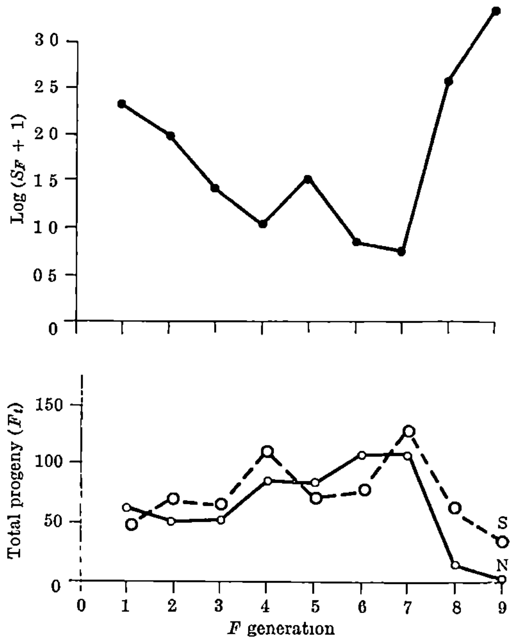

Fig 2 Generation series indicating inverse trends with solar flare activity (east (N)–west (S) orientation) Lower dashed line, progeny from culture on S pole, lower solid line, progeny from culture on N pole

than the S_1 curve The correlation coefficients listed in Table 1 also disclose greater negative r values for S_2 than S_1 data The series from magnet 1 is the only case (with east–west orientation) where the data from both poles disclosed r values below the 95 per cent level of significance Although S_1 shows a low r value a general inverse trend with solar activity is indicated in Fig 3

2	—0 14	—0 65

The inverse correlation of progeny grown in the magnetic field with solar flare activity suggests a possible influence from ionizing particles on factors controlling the productivity of *Drosophila* Ions with known charges have been shown by Krueger and Smith[3] to affect various physiological processes In the experiments reported here the magnetic fields are of sufficient strength to alter the air-ion environment in the regions over the poles Magnetic fields of the strength used here can be shown to influence the paths of incoming particles over a range of energies[4] It is further suggested that charged particles may be differentially selected over the pole regions Whether a given particle spirals into or away from a magnetic pole region depends on the charge of the particle, its direction and velocity and the strength and direction of the magnetic field The density of ions within the bottles, placed on the magnets, may be increased by high-energy particles being drawn into the field and producing ionization along their path These penetrating energetic particles may conceivably be associated with solar flare activity

At periods of intense flare activity the density of ionizing particles in the atmosphere is known to increase[5] High barometric pressures may, however, compensate for increases in ionizing particles by absorption in a more dense atmosphere During periods of high barometric pressure fewer particles reach the Earth's surface, and because of the interrelationship both the solar flare and barometric pressure parameters should be taken into consideration when comparing control data with progeny from cultures grown in the magnetic field

This problem was first considered by using controls or progeny grown out of the magnetic fields Progeny from control cultures show a correlation with barometric pressure, but do not indicate a significant correlation with S_F (equation 3) An illustration of these differences in correlation is given by the control series shown in Fig 4 plotted with the barometric pressures to show the corresponding maxima and minima As shown by the r values in Table 2 the correlation between progeny and P is significant whereas there is no correlation with the S_F factor (equation 3)

Table 2 CORRELATION COEFFICIENTS FOR CONTROL DATA FROM 16 GENERATIONS SHOWN IN FIG 4

Parameter (M)	r
P, barometric pressure (av)	+ 0 73
Log (S_F + 1) (equation 3)	+ 0 06
[P – log (S_F + 1) /10] (equation 4)	+ 0 80

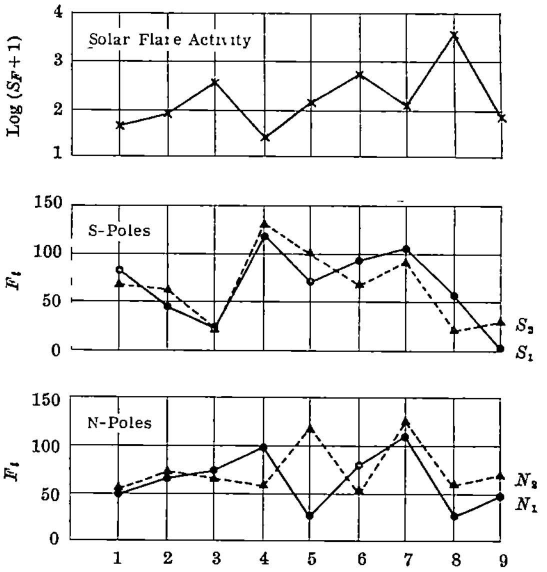

Fig 3 Progeny and solar flare data using two magnets (oriented east (S) – west (N)) on which cultures were grown simultaneously

An empirical relationship was worked out which incorporated both the P and S_F factors The equation is the result of various combinations and adjustments in the P and S_F parameters It is realized that with more exhaustive analysis this equation might be further modified and bettered , however, in its present form it did allow statistical comparisons to be made between the magnetic field and control data In this equation the flare activity is subtracted from the barometric pressure, the reason for this being the previously mentioned compensating effect of P on ionizing particles By subtracting the S_F function the effects are not minimized Expressed as a function of progeny this relationship is given by

$$F_t = K\,[P - \log (S_F + 1)/10] \qquad (4)$$

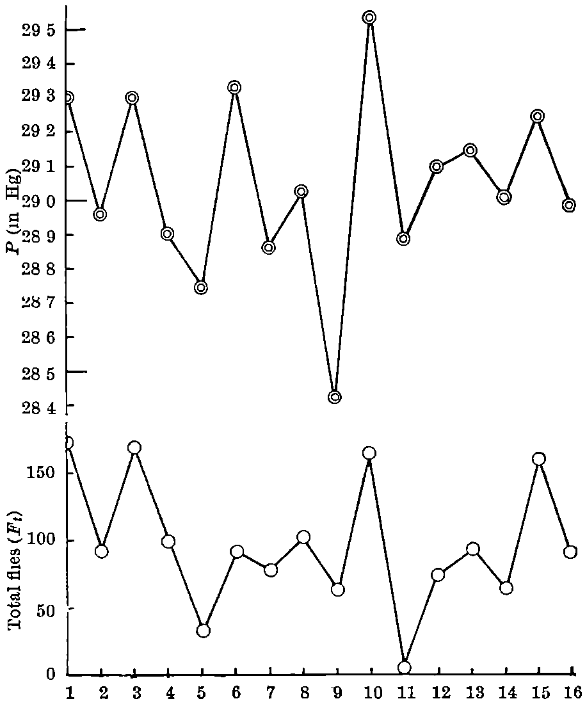

Fig 4 Control progeny (grown outside magnetic field) showing variations with barometric pressure (P is average of 72-hr period)

where K is a constant The solar flare function is divided by 10 simply to make the magnitude of the changes comparable to the tenths of an inch changes in barometric pressure As shown in Table 2 this equation gives about the same degree of correlation with progeny as when using only the P parameter

The application of the function within the brackets in equation (4) to magnetic field data is demonstrated in Fig 5 The solid line in the upper set of curves shows the flare activity function (equation 3) and the broken line the equation (4) relationship It may be seen that the empirical relationship (equation 4) varies directly with F_t whereas the flare activity, as in Figs 2 and 3, varies inversely Again the maxima and minima in the S pole curve in Fig 5 appear to correspond more closely with the maxima and minima in the upper curves than does the N pole results The correlation coefficients are given in Table 3 for the data plotted in Fig 5 and the t values substantiate the fact that the correlations are greater for the S pole results

Table 3 COMPARISON OF CORRELATION COEFFICIENTS USING FLARE ACTIVITY AND AN EMPIRICAL FUNCTION, MAGNET ORIENTATION EAST (N) – WEST (S) FOR DATA SHOWN IN FIG 5

$\log (S_F + 1)$		$[P - \log (S_F + 1)/10]$	
N	S	N	S
−0.36	−0.90	+0.04	+0.78

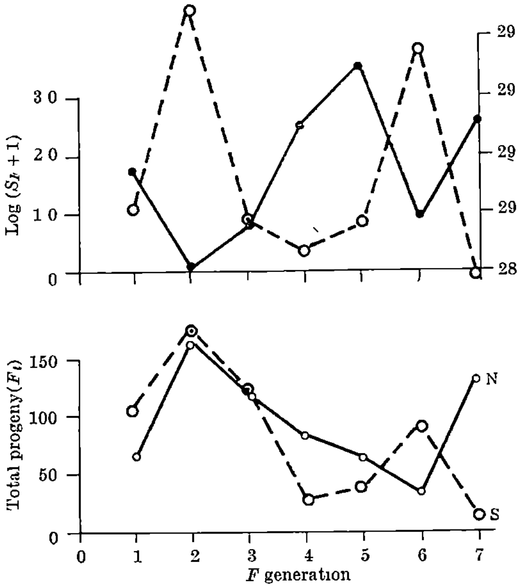

Fig 5 Magnetic field series (east (N) – west (S) orientation) Upper solid line, solar flare activity (equation 3), upper dashed line, empirical relation (equation 4) Lower dashed line, S pole progeny, lower solid line, N pole progeny

It should be pointed out that in all the magnetic field series, which have been discussed in detail the magnets were oriented in an east–west geomagnetic position Although many more series will have to be investigated, it appears that the inverse correlation between progeny and solar flare activity is much higher from the results obtained on east–west oriented magnets than with north–south Three series have been completed on magnets in the north–south position and the correlation with solar flare activity was below the level of significance in every case, in fact, the t values tended to be low and positive By using simplified conditions and the incorporation of the finding of an anisotropic distribution of particles arriving parallel to the orbital plane of the Earth[6] (general east-west direction), calculations suggest that the indicated orientation effect may be attributed to the manner in which charged particles encounter the fields surrounding the test magnets As these analyses become more refined and progeny data accumulate, it is hoped that the possible orientation effects, differences between the N and S pole results, etc, may be explained in a more rigorous manner.

OCCURRENCE OF SPREAD-F AT MAGNETICALLY CONJUGATE POINTS

By D G SINGLETON

Department of Physics, University of Queensland

RECENT investigations have revealed striking similarities between the occurrence of such geophysical phenomena as auroræ[1], very-low-frequency electromagnetic emissions[2], and magnetic disturbances[3] and micropulsations[2] at magnetically conjugate locations These phenomena are all connected in some way with the Earth's magnetic field The existence of correlation between conjugate points therefore suggests that the individual lines of force, stretching from the northern to the southern hemisphere, play an important part in the physical mechanisms which result in these phenomena Spread-F (ref 4) is another geophysical phenomenon which is dependent on the Earth's magnetic field, its occurrence correlates with magnetic disturbance[5] and varies in a systematic manner with geomagnetic rather than geographic latitude[6] It is of interest, therefore, to see if spread-F occurs simultaneously at magnetically conjugate points The existence, or otherwise of such a correlation and the implied importance, or otherwise, of the individual lines of force will obviously have important implications with regard to the formulation of a successful theory of spread-F

Because of the difficulty of obtaining direct access to ionograms of suitably located stations, the spread-F occurrence data had to be obtained from f-plots in a manner described elsewhere[6] Examination of the world-wide distribution of ionosonde stations which produce f-plots on a routine basis[7] reveals that the

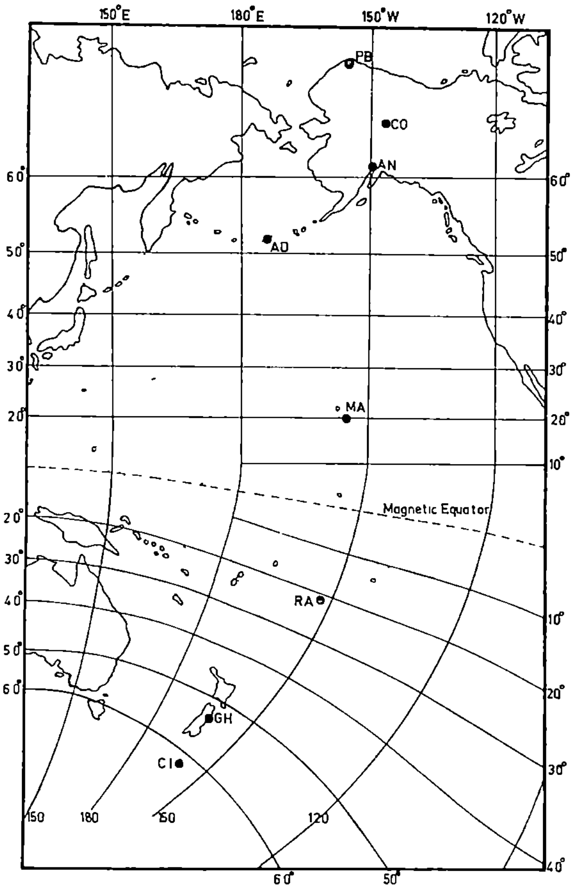

Fig 1

group of stations shown on the map of Fig 1 is the only group which contains stations which are nearly magnetically conjugate On Fig 1 the northern hemisphere grid of lines consists of the indicated lines of geographic latitude and longitude, while the southern hemisphere grid is the projection of the northern hemisphere grid to the southern hemisphere via the lines of magnetic force[8] How close Campbell Is (CI) and Anchorage (AN), Godley Head (GH) and Adak (AD) and Rarotonga (RA) and Maui (MA) are to being conjugate points can be gauged from an examination of Fig 1

Using the daily totals of hours in which spread-*F* occurred, Campbell Is , Godley Head and Rarotonga were correlated with their conjugate point stations and one or two stations north and south of their conjugate points The results of this analysis for the months of March, June and December 1959 are listed in cols 3, 6 and 9 of Table 1 With two exceptions (Campbell Is –Anchorage and Rarotonga–Maui both in December) the correlation between conjugate points is above the 10 per cent significance-level, whereas the correlation between each of the southern hemisphere stations and the stations neighbouring on its conjugate point station are either negative or positive and not significant These results suggest that the levels of occurrence of spread-*F* at conjugate point stations move together and that this connexion between the northern and southern hemispheres is limited to regions in the immediate vicinity of the conjugate points

The positive correlation of the daily totals of occurrence-hours at two stations does not necessarily imply that spread-*F* occurs simultaneously at the two stations It is, however, of importance from the point of view of the formulation of a successful theory of the formation of spread-*F* irregularities, to establish whether spread-*F* does occur simultaneously in the vicinity of magnetically conjugate points or not This has been attempted by applying a chi-square (χ^2) test to the night-time occurrence data Here the hypothesis is made that spread-*F* may occur in a purely random way at the two stations the occurrence data of which are being compared To test this, the presence or absence of spread-*F* on each hour of universal time at one station has been compared with that at the second in the usual way to obtain a value of χ^2 The resulting values of χ^2 for the station pairings used previously are listed in cols 4, 7 and 10 of Table 1 It will be noted that the values of χ^2 obtained are small except for the conjugate point stations for which they are, in the majority of cases, quite large The exceptions to this are Campbell Is – Anchorage in December and Godley Head–Adak in June The values in brackets in cols 4, 7 and 10 represent the probabilities that the departures of the observed distributions from the hypothetical random

The correlation coefficients (ρ) have a 1 per cent significance-level of 0 45 and a 10 per cent level of 0 30 + No result because of no occurrences at one or both stations distributions ($\chi^2 = 0$) could have arisen due to chance. It appears, therefore, that the hypothesis that the incidence of spread-*F* at one point is random and independent of that of another is false in the case of conjugate point stations but may be valid for the other stations compared

It has been demonstrated[9,10] that high incidence of spread-*F* is most likely when the critical frequency of the F_2-layer is low. It may be, therefore, that the apparent association between the incidence of spread-*F* at magnetically conjugate points is due to similar variations of this parameter at conjugate locations To test this the above χ^2 analyses were repeated using the spread-*F* occurrence data for only those periods when f_0F_2 was less than 6 Mc/s at both stations The resulting values of χ^2 and their associated probability figures (in brackets) are listed in cols 5, 8 and 11 of Table 1 It is immediately obvious that the apparent association between spread-*F* occurrence at conjugate points is dependent on the range of critical frequency considered This suggests that the coupling of spread-*F* occurrence in the northern and southern hemispheres, via the lines of force, is primarily due to the simultaneous occurrence over limited areas about conjugate points of periods when the critical frequency is low That there should be such large-scale coupling of *F*-region ionization at magnetically conjugate points has been suggested on theoretical grounds by Farley[11]

A more detailed account of this and other aspects of the correlation between the occurrence of spread-*F* at spaced stations will be presented elsewhere

I thank Prof H C Webster and Mr J Crouchley for advice and Mrs D. Neilsen for assistance with the calculations The *f*-plot data were kindly supplied by the Ionospheric Prediction Service

EARTHQUAKE SERIES IN ST. KITTS-NEVIS 1961-62

By Dr G. R ROBSON and K. G. BARR

Seismic Research Unit

AND

G W. SMITH

Soils Research Section, University of the West Indies, Trinidad

In November and December 1961 strong earthquakes were felt in Nevis and many minor earthquakes followed in the following months A few are occurring at the present time

The island of Nevis is formed for the most part of material erupted from Nevis Peak, a strato volcano, 3,200 ft in height The peak has a breached summit crater a little more than 1 km in diameter within which there is a small dome of hornblende andesite lava The later eruptions from the peak appear to have been of the ash-flow or 'nuée ardente' type, though none has occurred in post-Columbian times Recent gravity faults cut the youngest rocks, the displacements being such as to depress Nevis Peak Soufriere activity now occurs on these faults

In 1952 P L Willmore[1] described in *Nature* the earthquake series in St Kitts–Nevis in 1950–51 In 1950 the earthquakes began on December 27, maximum intensities (VII–VIII on the Mercalli scale) being felt in the western and southern parts of Nevis More than 150 earthquakes occurred in January 1951, and minor renewals of activity occurred in March and May Willmore arrived in Nevis early in February and his shock recorders were used to locate some of the March tremors, which were found to lie within the island, roughly north-west and south-east of Nevis Peak Willmore concluded that the activity never reached the stage when emergency measures to deal with an imminent volcanic eruption appeared to be required

In 1953, two years after this earthquake series, a new soufriere began to form at Cades Bay in the north-east of the island, and in 1957 the heat flow from this was about 4 × 10^4 cal/sec

Following recommendations made by Willmore at the request of the Colonial Office, the Seismic Research Unit was set up in 1952 with headquarters in Trinidad and equipped with a network of vertical component Willmore–Watts seismographs, one instrument being installed in each of the larger British islands in the eastern Caribbean

The recent activity in Nevis began with a strong earthquake on November 2, 1961, at 19.04 local time The epicentre of this earthquake is shown on Fig 2, the focal depth was about 10 km and the magnitude 6 3 Intensities experienced were VI–VII in Nevis and IV–V north of the south-eastern peninsular of St Kitts More than 80 after-shocks were recorded by the seismograph in St Kitts during the following five days Many of these earthquakes were felt in Nevis and some of them were felt in St Kitts

A second strong earthquake followed on November 7 at 19 40 h (Fig 2) The focal depth once more was about 10 km and the magnitude 5 9 Intensities were similar to those on November 2 Twenty-six after-shocks were recorded in St Kitts during the following ten days At the request of the Government of St Kitts–Nevis–Anguilla, Robson visited St Kitts on November 21 At this time no near earthquakes

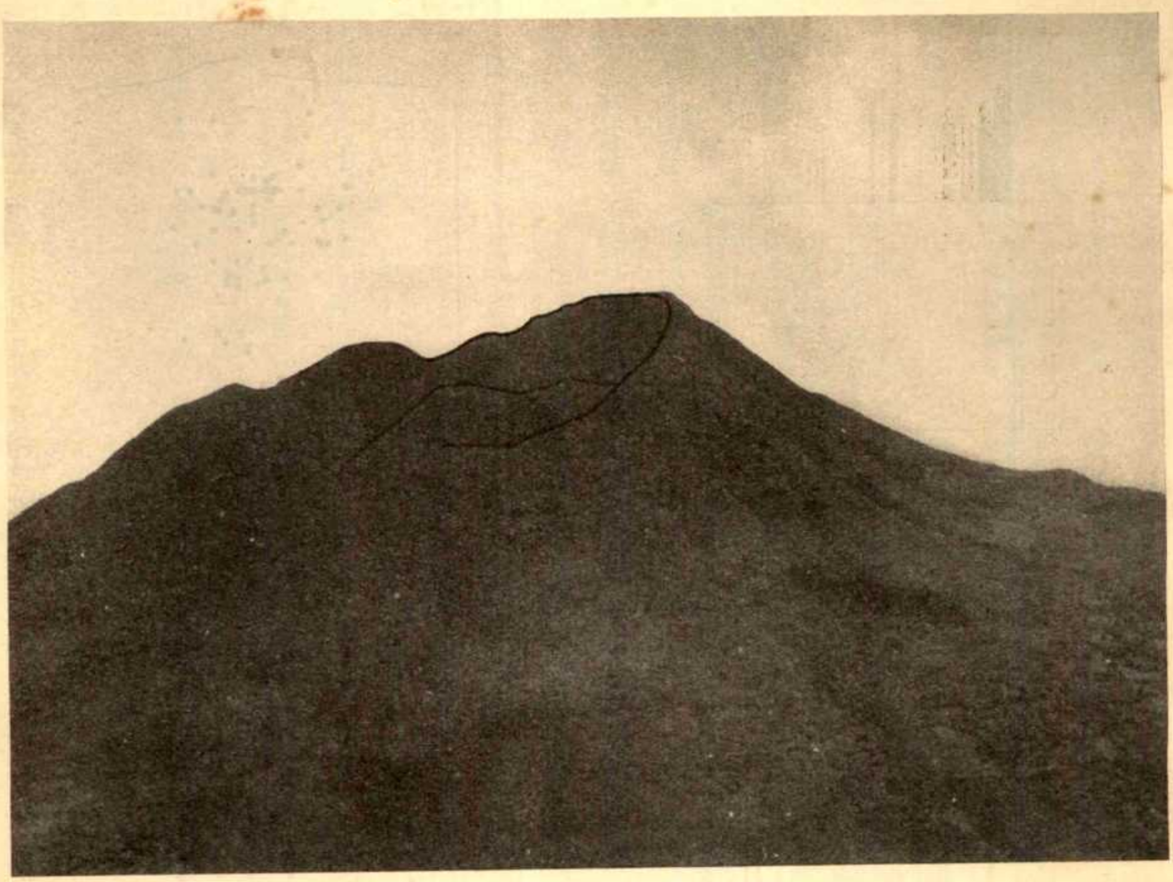

Fig. 1. Nevis Peak from the air looking north-east. The mountain is a strato volcano. A low dome of horneblende andesite fills the crater. The eastern rim of the crater forms the peak, while the western rim is breached and overlapped by the dome

were recorded in St. Kitts, and none was felt in Nevis. Cades Bay soufriere in Nevis was visited but there was no significant change in the heat flow from it. The Government was advised that no immediate action was required.

On December 14 a significant renewal of seismic activity occurred. Portable seismographs were flown to Nevis on December 19. These began recording on December 21 and are still in operation there.

The portable equipment consists of three Willmore 1-sec seismometers with low-frequency transistor amplifiers connected through telephone wires to $\frac{1}{4}$-sec galvanometers at a central recording station, which is equipped with a chronometer and radio. Differences in arrival times of earthquakes waves at the three stations can be estimated to 0·1 sec. Epicentre, focal depth and magnitude have been estimated for all earthquakes recorded at the three stations.

The shallow depth and short range of the earthquakes make it impossible to calculate magnitudes in the normal way. Instead, the observations of Carder and Cloud[2] and Romney[3] for explosions were used to compute magnitudes equivalent to Gutenberg's body wave magnitudes.

The results are shown in Figs. 3–5. The depth of the earthquakes varies from 1 to 11 km. It will be observed that the earthquakes recorded after December 21 do not occur close to the epicentres of the strong earthquakes of November 2 and 7 but are grouped about Nevis Peak. Furthermore, the energy released by these late earthquakes does not fall regularly with time as we have observed for after-shock sequences of strong earthquakes elsewhere in the eastern Caribbean. This has led us to suppose that these late earthquakes are not a simple after-shock sequence of the earthquakes of November 2 and 7 but that another factor is involved, in addition to strain release by the large shocks. It seems likely that this other factor is the presence of a body of magma beneath Nevis Peak, and that the Nevis Peak earthquakes are a result of changes in the shape

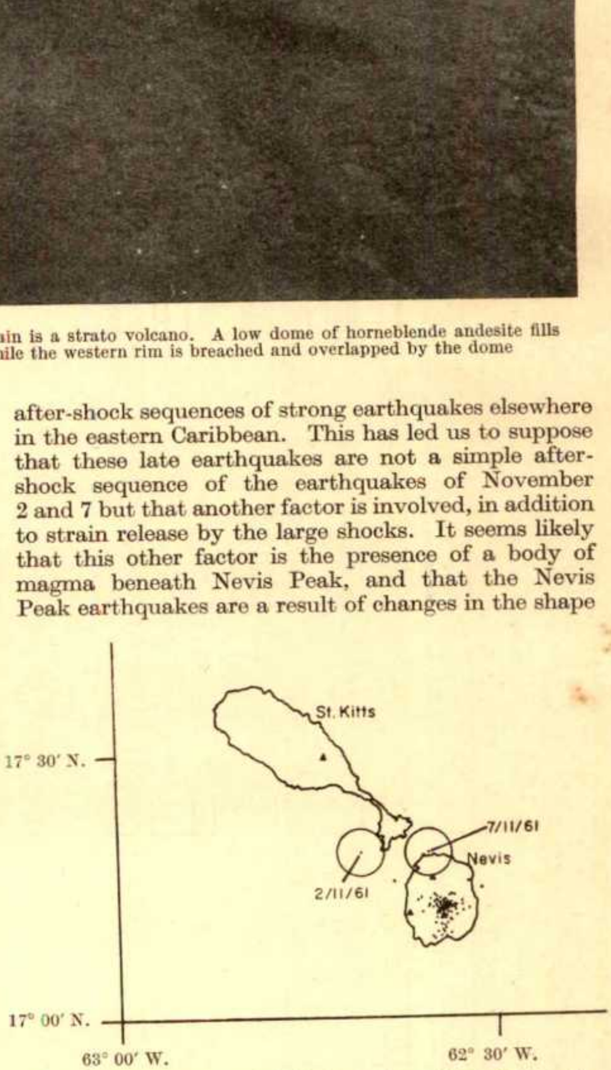

Fig. 2. Earthquakes recorded between November 1, 1961, and February 10, 1962. The circles indicate the probable error of the epicentres of the two strong shocks of November 2 and 7. Dots indicate epicentres determined by the portable equipment. The locations of the permanent seismographs in St. Kitts and the temporary stations in Nevis are shown by solid triangles

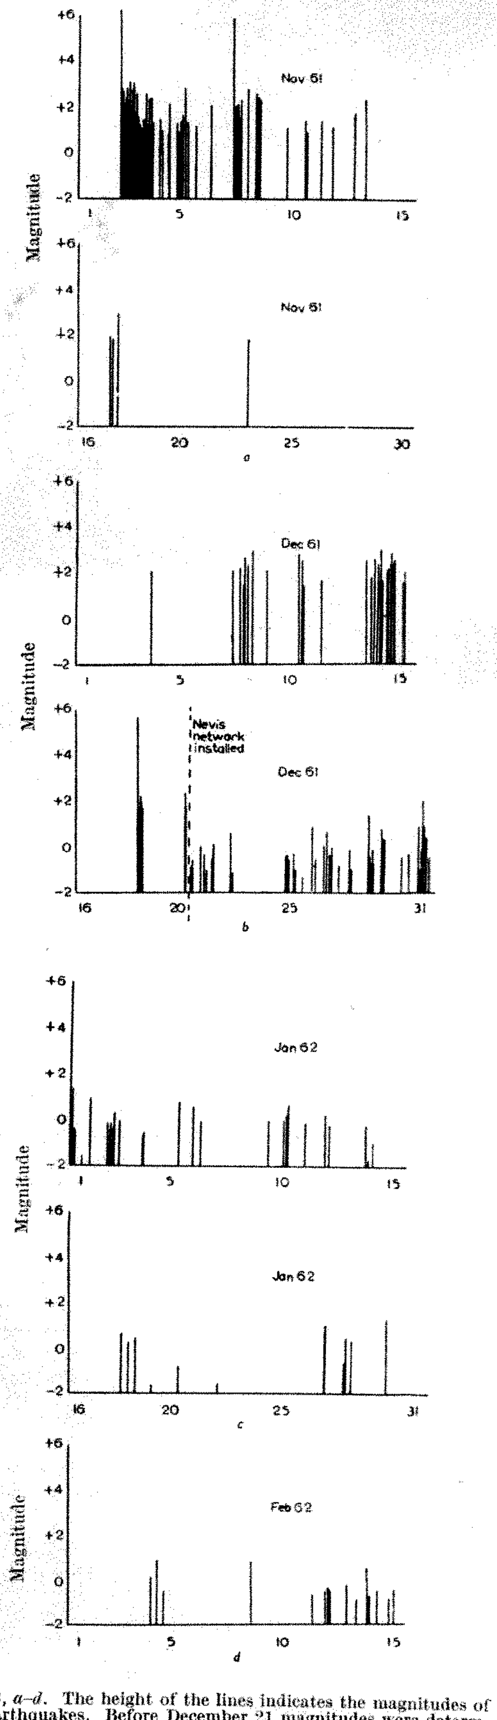

Fig. 3, *a–d*. The height of the lines indicates the magnitudes of the earthquakes. Before December 21 magnitudes were determined from records of the St. Kitts station or more distant stations

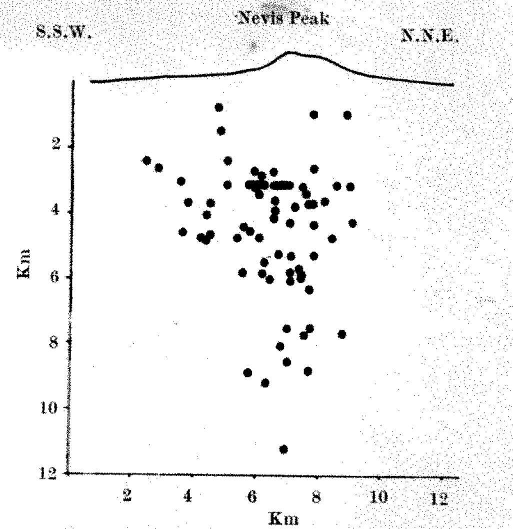

Fig. 4. All earthquakes projected on to a vertical north-north-east-south-south-west plane. Where depth could not be determined one of 3 km was assumed

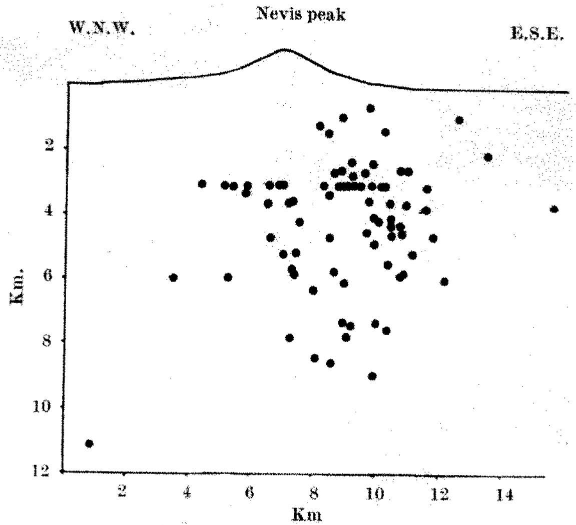

Fig. 5. All earthquakes projected on to a vertical west-north-west east-south-east plane. Where depth could not be determined one of 3 km was assumed

of this body in response to changes in the stress field within the surrounding rocks.

In its general features the present earthquake series resembles the earlier one of 1950–51. Both earthquake series began with strong shocks with epicentres west of the island which were followed by smaller shocks close to Nevis Peak.

We are now investigating the direction of first motion at the seismograph stations which recorded the large shocks in an attempt to determine the way in which the stress field in Nevis may have been changed. Further geophysical work, possibly gravity and magnetic surveys are desirable to test our assumption of the presence of a magma body and, if it exists, to attempt to determine its dimensions and depth.

We thank the Administrator of St. Kitts–Nevis–Anguilla, His Honour Lieut.-Colonel H. A. C. Howard, the Warden of Nevis, Mr. W. L. Maguire, and many Government officers for their assistance during the investigation.

AGE OF LUNDY GRANITE, BRISTOL CHANNEL

By M. H. DODSON and Dr. L. E. LONG

Department of Geology and Mineralogy, University of Oxford

THE granites which form the greater part of Lundy, a small island in the Bristol Channel, have generally been regarded as either Hercynian or Tertiary in age. A Hercynian age, that is, 270–300 m.y., would be expected from the geographical location of Lundy near known Hercynian granites of the Cornubian province. On the other hand, a Tertiary age (≤ 70 m.y.) might be expected because the granites are intersected by a dyke swarm which closely resembles swarms associated with Tertiary granites in Scotland and Northern Ireland. Dollar[1] favoured a Hercynian age on geographical, structural and petrological grounds. His principal evidence was a statistical comparison of chemical compositions indicating a decided similarity of the Lundy granites to the Hercynian granites as contrasted with the Tertiary granites. Bott *et al.*[2], however, showed from gravity data that the structure of the Lundy complex was more like that of the Mourne Granite (Tertiary) than that of the Hercynian granites in south-western England. Palæomagnetic evidence is compatible with a Tertiary (possibly Eocene) age for the dyke swarm but gives no direct evidence for the age of the granite[3].

An unweathered specimen of the intrusive phase designated *G*1 by Dollar (the earliest part of the complex) was collected from the southernmost quarry on the east side of the island. Potassium–argon and rubidium–strontium isotopic age measurements were made on separated biotite, and a rubidium and strontium isotopic analysis was made on a representative sample of whole rock (Table 1). In addition, a K–Ar age measurement was made on a slate sample collected at the south end of the island several hundred metres from the granite contact (Table 1). The slate is lithologically similar to the Upper Devonian Morte Slates in North Devon[1].

Table 1. ANALYTICAL DATA

Material	K (per cent)	^{40}Ar* (p.p.m.)	^{40}Ar* / Total ^{40}Ar	Rb (p.p.m.)	Common Sr (p.p.m.)	^{87}Sr/^{86}Sr$_t$†
Biotite	7·83	0·0294 0·0311	0·53 0·51	4,145 4,235	0·1 16·1	90 1·31
Slate	3·45	0·0437	0·89			
Whole rock granite				586	10·2	0·858
Slate (composite of two samples				37‡	79‡	0·730

* Radiogenic component. † Measured today. ‡ Emission spectrograph analysis by N. Garton.

The Rb/Sr ratios in both biotite and whole-rock granite are extraordinarily large for such materials, suggesting that the granite is either an extreme differentiate or represents the first-melting fraction of country rock. Other petrological data support this view. (The large discrepancy between the two determinations of common strontium in the biotite may be caused by an inhomogeneous contamination with a strontium-rich constituent of the rock such as apatite or fluorite. The determination of radiogenic strontium is not affected.)

The K–Ar and Rb–Sr ages of 52 ± 2 m.y. on the biotite (Table 2) suggest that the granite is Tertiary. However, from the biotite data alone it is not possible to distinguish between the alternative possibilities of a granite emplaced in Tertiary time, or a Hercynian granite which was re-heated about 50 m.y. ago causing radiogenic argon and strontium to be lost from the biotite. The K–Ar age of 170 m.y. on the adjacent slate contrasts sharply with ages of 300–350 m.y. obtained on similar slates in Devon and Cornwall[4] which presumably date the main period of folding and recrystallization. The apparent age of the Lundy slate, falling approximately midway between its presumed original age and the granite biotite age, is best explained as the result of a local source of heat producing partial loss of argon. The granite seems to be the most probable source of heat, but there is also the remote possibility that the Tertiary dyke swarm alone could have accounted for it.

Table 2. ISOTOPIC AGES

Material	Method	Apparent age (m.y.)
Granite *G*1 Biotite	K–Ar	52 ± 2 54 ± 2
Biotite together with whole rock data	Rb–Sr	53 ± 3 51 ± 2
	Average	52 ± 2
Whole-rock maximum age	Rb–Sr	66 ± 3
Slate	K–Ar	170 ± 6

Decay constants : ^{40}K : $\lambda_e = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$; $\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr.$^{-1}$
^{87}Rb : $\lambda_\beta = 0{\cdot}147 \times 10^{-10}$ yr.$^{-1}$

The whole-rock isotopic data unequivocally confirm the hypothesis of a Tertiary age. By assuming that the non-radiogenic, or 'common' strontium present in the granite at the time of its initial crystallization had the lowest conceivable ^{87}Sr/^{86}Sr ratio of 0·700 (primordial value found in achondritic meteorites), we calculate a maximum age of 66 ± 3 m.y. This age is still just Tertiary. Actually the assumption of an initial ratio of 0·700 is an unrealistically low choice, but the substitution of any higher value would give an even lower maximum age.

The isotopic data for whole rock and the least contaminated biotite (first analysis) are shown graphically in Fig. 1, following the method of presentation of Compston *et al.*[5]. The abundance of strontium-87, conveniently expressed as the ^{87}Sr/^{86}Sr ratio, increases with time due to the decay of rubidium-87. From the ^{87}Sr/^{86}Sr and Rb/Sr ratios measured to-day, and the decay constant of rubidium-87, the ^{87}Sr/^{86}Sr ratio at any time in the past may be calculated; conversely, if the initial ^{87}Sr/^{86}Sr ratio is known, the age of the rock or mineral may be calculated. Fig. 1 shows that the biotite could not have an age approaching the maximum limit for the whole rock since extrapolation of the biotite curve to 66 m.y. would correspond to a negative ^{87}Sr/^{86}Sr ratio—obviously an impossibility. The simplest hypothesis is that the biotite and rock as a whole inherited the identical ^{87}Sr/^{86}Sr ratio at the time the magma

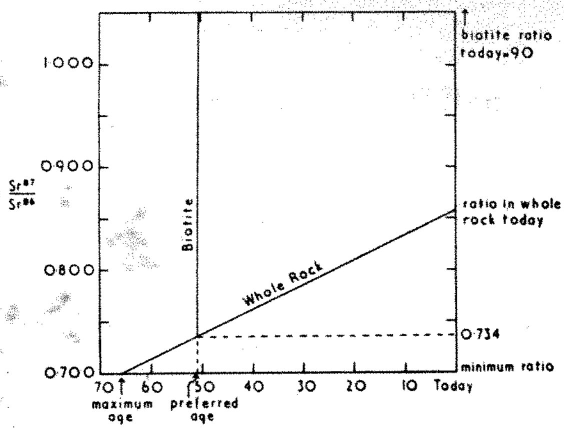

Fig. 1.

crystallized. This age, corresponding to the point of intersection of biotite and whole-rock curves in Fig. 1, is 51 ± 2 m.y., which is also in agreement with the biotite potassium–argon ages within experimental error. The granite could have crystallized earlier than that time, up to the maximum limit of 66 m.y., only if the radiogenic argon and strontium were expelled from the biotite slightly more than 50 m.y. ago. The intrusion of the granite *G*2 or the dyke swarm could produce a later heating which might accomplish such a recrystallization, but more likely for a small body such as the Lundy complex the time gap between intrusive phases was short.

The discussion so far assumes that the granite has been a closed chemical system for rubidium and strontium since its formation. A consideration of material balance demonstrates that if addition or subtraction of rubidium or strontium from the rock took place, the chemical change could not have occurred before the indicated maximum age of 66 m.y. Large-scale movement of rubidium or strontium could scarcely happen without corresponding movement of the associated major elements—in other words, the formation of a new rock in Tertiary time.

The $^{87}Sr/^{86}Sr$ ratio corresponding to the intersection of the biotite and whole-rock curves (Fig. 1) is 0·734 ± 0·005. Data regarding initial $^{87}Sr/^{86}Sr$ ratios in granitic rocks are meagre; nevertheless, this value of the initial ratio at Lundy is considerably higher than the typical values[6] of 0·71–0·72, and suggests that the parent material from which the Lundy granites were derived must have existed for a considerable length of time with a relatively high Rb/Sr ratio. We may therefore exclude the possibility that the Lundy granite was an extreme differentiate of a normal basalt magma, for basalts have very low Rb/Sr ratios, and $^{87}Sr/^{86}Sr$ ratios which are lower than the typical values for granites.

Considering the most probable alternative mode of origin for this granite, namely, partial melting of country rock, it is interesting to note the composition of strontium in the Lundy slate (Table 1). From this and the ratio of rubidium to strontium the $^{87}Sr/^{86}Sr$ ratio in the slate may be calculated to have been 0·728 ± 0·003 at the time of crystallization of the granite. This is not significantly different from the calculated initial ratio for the granite.

We conclude that the age of the granite is unquestionably early Tertiary, while on balance the evidence favours a date of emplacement of 52 ± 2 m.y., that is to say, Middle Eocene. Since *G*1 is the earliest part of the complex, the whole must be Tertiary. Therefore, Lundy represents the most southerly known Tertiary igneous centre of the North Atlantic Province. The petrological affinity between the Lundy granites and the Hercynian granites may perhaps be explained in terms of their geographical proximity.

We thank Drs. R. StJ. Lambert and N. J. Snelling for their assistance in collecting the material and in potassium analysis, and Dr. A. T. J. Dollar for helpful discussions. The work was performed as part of the programme of age determination in the Department of Geology and Mineralogy, Oxford University, under the general direction of Prof. L. R. Wager.

MEASUREMENT OF OCEAN BED CURRENTS

A NEW CHEAP METHOD AND A SUGGESTED PLAN

By Dr. J. N. CARRUTHERS

National Institute of Oceanography, Wormley,
Godalming, Surrey

THE increasing wish to learn everything possible about water movement on deep ocean floors may perhaps lend interest to a simple and cheap method recently used with complete success from the research vessel *Sarsia* of the Marine Biological Association of the United Kingdom. The method, which provides for single observations only, is easily operable from a drifting ship and has been developed with a further step in view of which some account is given here.

The deepest of three observations made on June 5 and 6, 1962, was at the position 46° 7′ N.–8° 25′ W. beneath 2,250 fathoms (about 2½ land miles) of water. The position, which was fixed by Decca, lies about 160 miles from Ushant Light in the direction 240°. Earlier, the two equally successful single observations of on-bottom current had been made on the shelf edge, the first at the position 47° 49′ N.–8° 13′ W. below some 950 fathoms of water, and the second at a station sounding some 1,400 fathoms at 47° 20′ N.–8° 15′ W. The echo soundings quoted are approximate averages for the initial and final positions of the drifting ship.

At the deepest station where the echo sounding changed very little indeed during the ship's drift, a bed current running towards north-north-west (mag.) at 5 cm./sec. was observed. At both the other stations which lay alike on a markedly sloping bottom, the current was towards south-south-west (mag.) at the speed of 4 cm./sec.

It is very easy indeed to make quick single observations of sea-bed currents down to depths of about 60 fathoms from a drifting ship with virtually no concern at all for weather[1], and, for a few years back, there has been no difficulty while drifting, in making single observations of on-bottom current below depths ten times as great (and more). This has been possible by using a simple leaning-tube current indicator which is operable without more dependence on weather than applies to routine water-bottle work[2]. It was because that earlier leaning-tube device had a depth-of-use limit that the new method to be described was developed. What the earlier depth limit in question is has not so far been precisely determined, but it lies at between 1,600 and 3,000 metres submergence. With the previous method[2] the single observations made on bottom were easily repeatable hourly at depths around 600 fathoms. If they had been made as deep as possible, the repetition-rate would necessarily have been much slower.

The new device, which produced the three results already given, is also a leaning-tube current indicator —of great sensitivity—but its use need have no depth restriction at all. The functioning of its precursor depends on the setting of an oil-surmounted jelly which leaves surface very hot in a 'Pyrex' bottle surrounded by an envelope of hot water. This latter has to remain warm enough to keep the jelly mobile until it (the envelope) is voided on bottom being reached. The new all-depths device functions after the solution of a strange kind of tablet, which is protected from the sea-water during descent. This protection is given by an initial surround of kerosene to be later voided. The perfect tablet for the purpose needs to preserve great strength until such time as water is allowed to get at it. It must also have the desirable solution times for all temperatures in which it will be used. After much delay due to unsuccessful trials with various kinds of expensive solution tablets in vogue, the perfect tablet was found to be a common sugar-lump painted in a certain way Using celluloid enamel, four sides of the lump were painted over to leave two opposite sides only white. For this, a small bottle of crimson nail varnish with its own little brush was very convenient.

Many dozens of the painted cubes were prepared, and an adequate number of them were tested for solution timings under the exact conditions in which they would be used. Tests in sea-water varying from 0° C. to 13° C. showed excellent repeatability with a range of about 12–6 min. Next, it was proved that the painted lumps were unaffected by submission to pressures simulating 4½ miles of submergence—this while immersed in kerosene.

All that needs to be said in this first description of the new simple device and its operation can conveniently be related to the two accompanying illustrations. The main item is a 40-in. long polythene tube 4 in. in overall diameter and of wall thickness ¼ in. This is sealed near one end (to become the base) by means of a welded-in disk of polythene a couple of inches or so up. A tether of thin strong cord is tied into a peripheral hole very near the base below the sealing. Into a second hole dead across from the tether hole, one end of another light cord is secured and its free part passed through a short length of brass tubing. This is of just the right weight to make the buoyant tube (loaded in a way as will be described) stand vertical when flooded with and submerged in still sea-water under the following circumstances. The tether is secured at a length of about 6 in. to a weight easily able to sink the flooded tube, and, at the same time, the cord passing through the brass tubing is led upwards, is cut short to about 6 in., and is then tied at its free end into the bottom loop of a highly stretched rubber band the upper end of which is fastened into a hole in the top rim of the polythene tube 180° away from the basal tether hole. Thus, the brass counterpoise tubing becomes a sort of spine to the tube when it stands erect in motionless sea-water. If, after careful adjustment for erect posture in still sea-water, the tube tethered to a sinker were thrown into moving sea-water just deep enough to submerge it, it would be seen to have fore-and-aft properties; it would lean over with the spine away from the current. Secured into the top of the tube is a directional inclinometer the nature of which can be made out from Fig. 1. The basal disk of this, which is a neat fit within the tube, has a few holes bored in it to permit the passage of water through it smoothly and slowly. The side bars of the inclinometer can easily be tied at their tops into the polythene tube by means of a thin twine passed through facing holes in them and the tube top. The fore-and-aft direction of the inclinometer has, of course, to match that of the tube when secured into it.

The inclinometer possesses a free-hanging pendulum of directional nature. This is contrived from a terylene thread which runs loosely through a small plastic sleeve forced jam-tight at one end into a vertical 'hole' running centrally through a powerfully magnetized ceramic disk flashed across the diameter. The emergent end of the thread is tied securely around a tiny bar of wood which is 'glued' tight to the disk bottom with a dab of waterproof cement. The magnet disk, enamelled white overall, carries four coloured stripes as indicators of direction—red for north-seeking, blue for south, green for east and yellow for west. The stripes run across both faces of the disk and down its side. The free end of the thread passes up through and is secured into a smooth hole bored downwards at the mid-point of a non-turning 'axle' which carries two non-turning disks made (as is the entire inclinometer), of white hard and buoyant polypropylene. These plastic disks are spring-loaded on their sides nearest to the upright side-bars—the springs being powerful and of phosphor bronze. Unless these disks are held apart, they securely grip the plastic sleeve on which the circular magnet cannot turn in the least degree. In practice they are forced apart as far as possible and are held fully agape by means of a small snatch-away bar (also of hard plastic) which is inserted between the disk rims at their topmost part. The length of the terylene thread is cut to ensure that the circular compass hangs free—but only just free—of the rims of the gripper disks at their lowest part. To ensure that the pendulum length remains constant—as it must—special provision is made to obviate small changes in length when the inclinometer is tilted. But for such provision the length would shorten a little when a portion of the thread bore on the non-turning 'axle'. Constant length is arranged for by making a suitable cut into the axle bar below its mid-point just beneath the hole up through which the

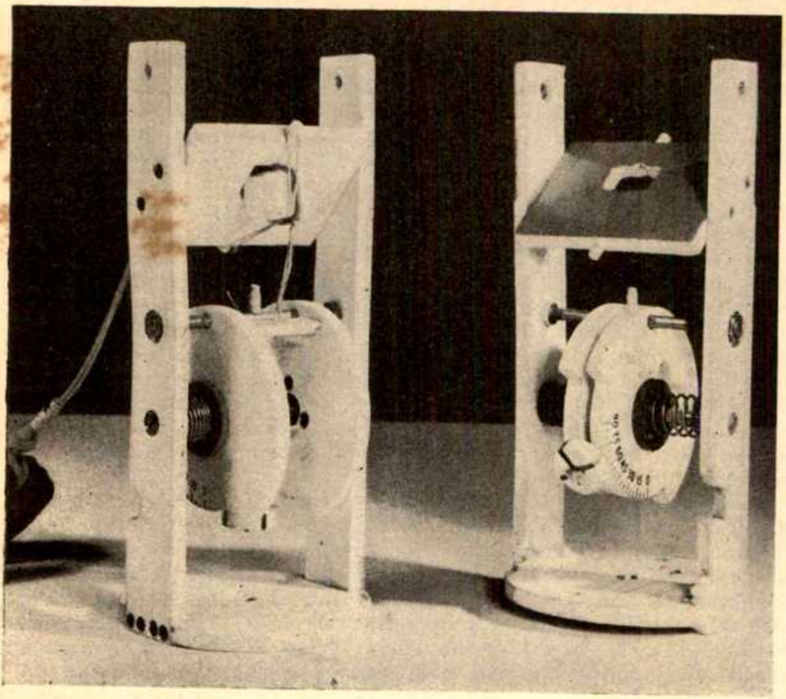

Fig. 1. The directional inclinometer. Cocked on the left; sprung on the right

terylene thread passes. The latter is easily fixed for precise length because, above the hole in the non-turning 'axle', there is a tiny soldered-in brass tubelet standing upwards. The thread is led up through this and is then easily secured in position by leading it down the side of the tubelet and snugging over it a short length of tight-on plastic sleeving.

With the gape-bar in position and the pendulum consequently free to stay always vertical, the first step is to cock the inclinometer. Near the top of the side-bars, a plate is fixed between them sloped at 45°, as seen in the photograph. In this is a rectangular hole into which (at its lower side) a painted sugar-lump is pressed edge-on to leave the two opposite white sides in the fore-and-aft line. The lump is held in position by means of a tiny rubber band during the preparations. Through the rectangular hole passes down from above a loop of thin polythene braid. This, which is placed around the sugar-lump, is in strong tension due to its being in connexion with the spine cord already referred to. This cord, which passes over a nick in the top rim of the polythene tube, is bent into a rubber stretcher which runs externally down the spine of the tube and serves not only to exert a strong pull on the sugar-lump but also to keep the brass tube counterpoise weight vertically up the spine. At the top of the brass tube there is a hook which provides that tension can be put on at the last moment. The drag loop can be put around the sugar-lump while the cord is loose because the tiny rubber band keeps the lump from falling out of position during the cocking.

Before the inclinometer in its fully gaped state is secured into the tube, a pull thread is tied slack between a hole in the small gape-bar and the underside of the loop which passes around the sugar-lump. When the gaped inclinometer has been secured into the top of the tube, the tension link is stretched and the cord hooked on at its far end above the brass counterpoise tube. The situation now is, of course, that there is such a strong pull on the tablet that if it suddenly sublimed the loop would be snatched up through the rectangular hole and would pluck up the gape-bar so suddenly that the pendulum would be instantly clamped.

Before the tube assembly as so far described was taken to sea, calibration tests were kindly made at the National Physical Laboratory to relate tilt-angle to current speed, and in this connexion it should be mentioned that the inclinometer carries a graduated scale. The device is very sensitive indeed and cannot serve in its present form for currents above one knot; its competence effectively falls away at less than that speed in fact. Visits were paid to a river affording a wide variety of flow directions, and checks were made that the pendulum of the leaning tube indicator in its new form always clamped to show the known current direction. Subsequent tests in a very turbulent mill stream were also most reassuring in affording evidence that the closure of the inclinometer, now that it is so sudden, takes place without the falsification of direction which characterized an early model when, with slow closure, the pendulum could be rolled out of direction as the tube surged.

It is now time to say that the tube is sent down into the sea with most of its length filled with sea-water dipped from overside. The top portion, of length equal to that of the inclinometer, is filled with common kerosene. Then, using a 1 ft.^{2} of high-quality rubber sheet, the latter is placed on top of the tube and stroked tightly down the sides using both hands. Next, a high-quality long flat rubber band is stretched by a helper and affixed under strong tension around the rubber capping in three winds. At this stage, the tube itself is ready for use. Because of the fact that kerosene attacks natural rubber, it is advisable always to use a new rubber capping and band for each observation. It is not satisfactory to use oil-resistant artificial rubber because of its inferior stretch properties, and there would be disadvantages in the use of vegetable oil instead of kerosene in order to avoid the attack.

The way in which the device is used can be made out from comments on Fig. 2. The customary thimble is chopped off the end of the ship's hydrowire and this is then led through a snug hole at the finely coned steel top of a long narrow iron weight. It is passed on through a hole running the full length of the latter and the emergent end is bulldogged into a loop too big to pass the hole, but small enough to snug into a basal recess in the weight. The weight used from R.V. *Sarsia* weighed about 1 cwt. and was about 5 ft. long without any whip at all. The illustration shows an alternative plummet. This is a length of old chain weighing about 10 lb. per foot, and a 10-ft. length of it was carried for use in case of loss. If such a cheap ready-to-hand plummet be used it has to be fitted with a nosecap at its top to surround the attachment to the hydrowire smoothly. The nosecap shown covers a link or more of the chain.

and the wire fits snugly into the hole drilled through it. The practice is to pay out the bare hydrowire until the heavy plummet will be hanging freely at a suitable distance above the ocean bed. With a long length of wire veered, it is, of course, far from easy to place the plummet at a desired height above the ground—especially when working from a ship which cannot steam up to the wire to keep the visible portion of it sensibly vertical. This is the case with R.V. *Sarsia*. If the work had been in train from a vessel which can edge into the wire, the decision what length of wire to pay out would have been easier.

There is, of course, a modern pinger method which makes possible the keeping of a suspended instrument at a desired small height above a deep ocean bed, but that is an expensive accessory usable only from a sophisticated ship. For the new operation being tried for the first time, it was not necessary to know with any precision how close an approach was made to hanging the plummet some ten fathoms above the ocean bed. It did not matter what the distance was—5–50 or more fathoms. In the event, we had proof that we had chosen our wire-length successfully—as will be told.

If time had served, it would, of course, have been easily possible to make a preliminary lowering with a waterbottle attached just above the plummet. The reversal of the usual thermometers would have resulted in the achieved depth becoming known. Alternatively, one could have measured the shape of the hydrowire at a number of points down its length using suitable messenger-operated inclinometers.

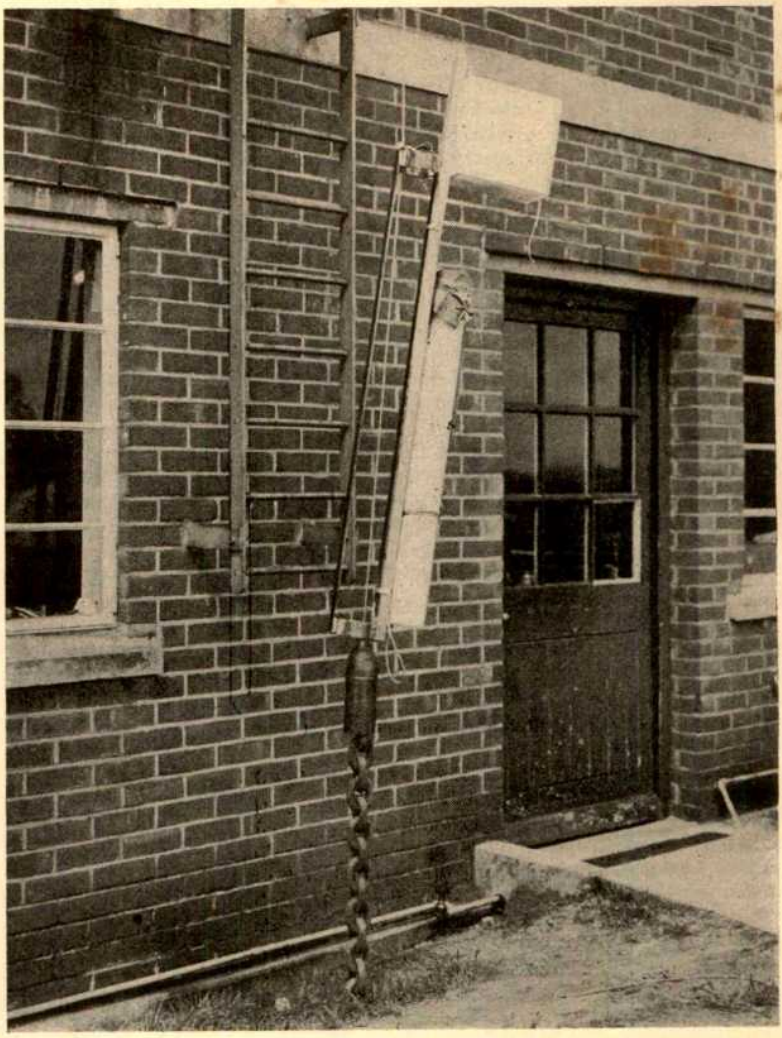

Fig. 2. The total assembly sent messenger-wise down the veered hydrowire. The frame is shown resting on the nose-capped chain plummet over which it passes freely in practice

Once the plummet is down hanging alone and freely at the end of the chosen length of veered wire, everything else used is slid down the wire like a giant messenger. The total assembly is shown in Fig. 2. A couple of 2-in. rings cut from a steel pipe of strong wall and 4-in. aperture are welded terminally on to two steel bars in such a way that the rings are about 4½ ft. apart and the bars 180° apart. The bars are on the outside of the rings so that the latter have no projections within. Half-way between the bars and on the same side, each ring has a saw-cut made in it of size sufficient to admit the hydrowire. At either side of each cut there is a hole. Having made ready a couple of square-bent staples of stout common galvanized wire, it is possible to place the simple framework on to the hydrowire and then to pass the legs of a staple out-from-in through the holes. Having bent the emergent legs over flat against the exteriors of the rings, the framework could not leave the hydrowire if allowed to run freely down it. Fastened tightly to that steel bar, destined to be the uppermost when bottom is reached, is a long square-section bar of substantial hardwood the function of which is to make screw-in and screw-on attachments easy. On to this wooden bar near what is to be the bottom end of the framework a small brass eyeplate is screwed. Into this eye the tether of the polythene tube is tied at a length of some 6 in. Near the top of the wooden bar, a rectangular free-flooding (because holed) box welded up from polypropylene sheet is screwed on. This box contains a large smooth spool made entirely of the same material but without an axle. It is just shake-free within the box and on it is wound something more than 400 yd. of nylon braid of breaking-strain about 600 lb. One end of this braid emerges from a slot cut in the side of the box nearest the top, and is passed through a smooth brass eyeplate fixed near the top of the wooden bar.

When the frame is first placed on the hydrowire it is, of course, held up at rail-level by a castaway rope until all is ready for slipping. Because of the weight of the box of cord, the frame leans on the hydrowire in such a way that the edge of the steel frame ring away from the box presses tightly on it. This situation permits that a heavy steel shackle of aperture too small to pass over the plummet can be fixed round the wire at that point without any risk of it falling down within the frame when this latter will slide freely down the wire to shoot easily off the plummet and dive for bottom. Into this shackle the emergent end of the nylon cord is tied after passing through the brass eye spoken of. Of course, the nylon cord is secured firmly to the spool at its other end. On the tether side of the polythene tube there is a small welded-on plastic eye open up-and-down. This, about 1 ft. from the top, comes between two brass eyes screwed into the wooden bar when the tube is pressed against the latter. These eyes are also open up-and-down. Using a yard-long piece of stout but bendable smooth steel welding-wire, a loop twisted in its top is secured to the shackle. For convenience I shall refer to this wire as the 'skewer wire'. A seized curl is now made in it a distance down it (as it hangs) to come up against the polythene tube just above the position of the upper screw-eye seated in the wooden bar. The length of skewer wire below this curl is passed down through that upper screw-eye, down through the plastic eye, and on down through the lower screw-eye to project some 6 in. below the latter. The tethered, cocked and filled tube is now held securely against the bar to keep it under control during descent.

Using a 2-ft. length of thin but strong slippery polythene braid, one end of this is tied round the outer wind only of the rubber band which holds the rubber capping on to the tube top. It is pulled down somewhat to keep the rubber band bowed down a little, and is then knotted while drawn tight round the projection of the skewer wire below the lower screw-eye. The free end is then led up and tied slack into the seized curl of the skewer wire.

All is now ready for letting the entire assembly slip away to run freely down the hydrowire. With the arrangements described there is no problem such as would exist if two large units had to separate at the bottom. By putting everything on the bottoming frame apart from the shackle, there is no risk of premature separation during descent. There is also no need to provide an infallible mechanism to achieve separation between what has to go down to the ocean bed and what has to stay up on the hydrowire. Most important of all, the arrangements described, besides being very simple, avoid the risk of two distinct units separating somewhat during descent with the consequent likelihood of fouling due to unequal or unlike rotation round the hydrowire.

When the assembly reaches the plummet, the framework runs easily over it. Because the shackle cannot pass over the plummet, it results that during the free dive to the ground a length of nylon cord is pulled out from the spool box. It will doubtless have been realized that any small risk of the shackle being left behind somewhat during the descent of the assembly down the hydrowire is prevented by the fact that the skewer wire which constrains the tube to the wooden bar cannot lift. Because of the way in which the tie from the rubber band is made, there is enough hold-down of the skewer wire fastened at its top into the shackle to ensure that this latter stays in its initial position until the plummet holds it back.

From the descriptions given here it will be seen that when the framework passes over the plummet two distinct things must happen. The constraint of the tube against the wooden bar is released, and the rubber cover is pulled off the top of it. This, of course, voids the paraffin oil, whereupon the sugar-lump is no longer protected against solution. The rubber cover cannot fall into the tube to cause trouble because a small crocodile at the free end of the twine tied to the rubber band is clipped to a corner of it initially.

During the free fall of the framework to bottom after passage over the plummet, the kiting effect of the released but tethered tube will keep the wooden bar uppermost. The box will also contribute to this. Once the thing is on bottom the nylon cord will pay out from the box as the ship drifts because the frame acts as an anchor. Before all the cord has run out the sugar-lump will have dissolved and the inclinometer will have functioned to record slope and direction before the leaning tube is disturbed. At the end of the run-out, the travel of the hanging plummet through the water above will, of course, impose a drag on the bottomed gear, but there will be a lifting component in this. It results that the frame is not towed bodily along the ground with serious risks of loss. It commences by being towed lightly on its heel, that is, on the edge of the steel ring remote from the cord, and finishes without doubt in then being towed harmlessly through the water off bottom altogether. That this desirable state of affairs is not guesswork was tested in an age-old way; the frame was coated liberally with greasy paint before use. As regards this likelihood of harmless off-bottom kiting when the cord draws tight on the bottomed gear, it has to be mentioned that when the cord box has only the empty spool left within it, it and the spool become buoyant enough in conjunction with the buoyancy of the polythene tube to exercise enough lift on the wooden bar to urge it upwards. Overside tests made with no cord in the box and with the frame hung from both ends, showed that just before drag comes on it as it lies on the ocean bed, the wooden bar side must be resolutely upwards. It was a fortunate circumstance that the ship was light during the short cruise. This gave her pronounced leeway assessed at 1 knot during the least-deep observation and at $\frac{1}{2}$-knot during the other two. In all three cases the drift decided from Decca fixes was towards south-south-west. Had the cord not paid out properly during the free dive of the gear on to the ground, the inclinometer would have evidenced a 'current' equal to the drift speed and in a north-north-easterly direction. Equally, if, after reaching ground, the frame had been pulled into movement before the sugar dissolved, there would also have been evidence of a 'current' towards north-north-east.

Everything pointed to correct functioning and to the fact that weights, timings, dimensions and cord-length had been happily chosen.

It was, of course, essential to know that the gear reached the plummet in the same state as it left the surface, that is, that the rubber cover had not washed off during descent. To check on this a stop was put atop the plummet over which the frame could not pass. The made-ready gear was then allowed to run down freely to different depths. Because the shock of arrival at the plummet could now be felt in the hydrowire, we also got our descent timings in this way and learnt that 45 min. should be allowed for a run-down of 4,000 metres. Each time that we brought up the un-tripped gear it was seen that the rubber cover was still secure on the tube top and that the sugar-lump had remained in its pristine state surrounded by kerosene of initial volume. Tests were also made to learn the time of free-fall of the gear after its overshooting of the plummet The entire assembly with the cord bôx full was tossed overboard on a measured line and was found to fall through the water at about 1 metre per sec This means, of course, that a free fall of 100 metres below the plummet would cut the life of the sugar by well less than 2 min because the kerosene would first have to be flushed from the tube and forced out of the sugar-lump as well

Clearly, adaptations could easily be made to suit the individual tastes of would-be users of this method of observing ocean bed current The run-out cord could be made as long as wished within reason In these first trials we pulled the cord in by hand after having hauled in the plummet, but, with a powered reel it could easily be brought in to any length chosen If the intention were to work the method under conditions of very brisk leeway indeed, it would be useful first to moor a buoy on tight scope in the modern way Then, if the ship were not allowed to fall further away from the buoy than a distance represented by the length of the run-out cord, all chance of dragging would be avoided For the observations under report we had allowed for at least a 12-min drift at 1 knot

Particular usefulness for the new simple technique is seen in connexion with observations on canyon bottoms and on rough difficult bottoms generally where there might be natural reluctance to use expensive gear likely to be lost For such work in restricted areas there would be particular need for a tightly moored buoy so that repeat observations could be made at just the same place each time There remains need for a remark on the time taken to make such observations as those reported

At the deepest station sounding 2,250 fathoms, the time occupied between plummet away and tube inboard was about 3½ hr , but this could presumably have been cut to 3 hr if the cord had been wound in on a powered reel

Future Possibilities

Though it is intended to use the method here described when knowledge of deep-bed currents is wanted on the spot, so to speak, an obvious next step of great promise seems indicated

The method described here provides only for single observations, and perhaps only very few repeats per day would be possible in the deepest water The likelihood of making much use of continuously recording instruments beneath the greatest depths is scant, and, even if such use were possible, expense will be only one drawback Always there looms the great question of space coverage The oceans are so vast that to learn everything about the bed currents at just one abyssal spot would be of sorely limited value though a great achievement of compelling interest

It is possible to suggest with confidence a scheme of work which would achieve great coverage in both time and space at very modest cost and but little trouble in this important field of studying ocean bed currents There is a proviso, one would have to forget the clock and would have to be content not to know what happened at precise hours. This accepted, the scheme to be suggested could, over great areas of ocean, build up data towards revealing what speeds and directions of bed current *ever* exist

It would be easy to make a cheap expendable form of the leaning-tube current indicator This would be made of the cheapest possible material resembling polythene in point of maintenance of *in situ* buoyancy under great pressure There would be no wires nor lines, no kerosene, and no rubber cap, and the simple instruments would be supplied to all manner of ships merely to be thrown overboard at desired positions of which a record would be kept The solution tablet would be a very long-lasting one to the end that there would be such a wide and random spread in the clamping times of the devices that all fluctuations more or less might be expected to be covered in time The tether could be a short length of string tied to a brick (for easy stowage) and each tube would have an identity number for record Once tossed overboard it would sink to bottom to put on its single record after quite a long sojourn there It would stay on the ocean bed until, consequent on the 'rotting' of the string, it rose to surface to float freely until such time as cast ashore Many would certainly be found, and the requisite information sent in as with drift bottles There would be provision that the record clamped into the inclinometers for direction and speed could not be destroyed by the finders A multi-language questionnaire sheet of printed polythene could be enclosed telling the finder to take his finding to the nearest police station The tubes could, of course, be vividly striped to facilitate discovery of them after stranding

There would seem to be no real difficulty in sowing far and wide over the oceans from ships of every sort and description, large numbers of a cheap version of the leaning tube indicator which would sink to the deepest ocean bed, there to put on a registration of water movement, speed and direction, to be later brought up to the surface for onward transmission by 'Bottle Post' Great boons of such a method of investigation would be the complete escape from expensive ship time, the fact that sowings could be arranged for wherever ships of any kind ply, and the absolute certainty that the records would not be falsified from above since there would be no attached lines whatsoever It could be expected that if enough such instruments were thrown over on enough occasions at such a interesting place, say, as the Puerto Rico Deep, then, with the passage of years, revelation would come as to what speeds and directions of bottom current ever exist there Quite certainly adequate returns would come from north-west Europe One attraction of the suggested plan is that there would be no concern at all for weather It seems reasonable to suppose that as much money as would run a big research vessel for a day could be rewardingly applied to what has just been advocated

There seems no reason to doubt that the scheme could be profitably tried in any area of ocean

The pursuit of knowledge always benefits from a leaven of excitement, and who would not be excited to learn from an object found stranded on an Icelandic beach, what the bottom current had been a couple of years earlier at a spot in the Caribbean Sea ?

Thanks are tendered to Dr F S Russell for kindly placing R V *Sarsia* at my disposal, to Captain C A Hoodless and his ship's company for much help generously given, and to my colleagues Messrs L A Baxter, C L Gulliver and J W Bicknell, on whose help at sea the work depended

FARADAY ROTATION OF POLARIZED GALACTIC RADIO EMISSION

By R. WIELEBINSKI and DR. J. R. SHAKESHAFT

Mullard Radio Astronomy Observatory, Cavendish Laboratory, Cambridge

RECENT work[1-3] has revealed the apparent existence of a small linearly polarized component in the 408-Mc/s radiation from certain areas of the sky. Linearly polarized emission is associated with the acceleration of relativistic electrons in a magnetic field, the mechanism which is generally believed to be responsible for most of the galactic radio emission.

The methods of observation both at Leyden Observatory[1,2] and at the Mullard Radio Astronomy Observatory, Cambridge[3], makes use of two mutually perpendicular dipoles rotated about the axis of symmetry at the focus of a paraboloidal reflector. The degree of polarization is then determined by measuring either the correlation between the voltages induced in the dipoles (Leyden) or the difference between the powers intercepted by the two dipoles (Cambridge).

Both methods suffer from limitations set by irregularities in the reflectors and dipole supporting structure, and by the reception from off-axis directions of radiation from the ground and sky; such radiation may in some circumstances appear to be almost completely polarized, and careful corrections have been necessary in both series of observations in order to isolate the true polarized signal from these spurious and often larger effects.

Although the substantial agreement between the two sets of observations strongly suggests the presence of a true polarized component, the corrections required are sufficiently great to make an independent test desirable. A series of observations has therefore been made to detect the Faraday rotation of the plane of polarization due to changes of the electron content of the ionosphere. This method was first used by Thomson[4] with inconclusive results and has also been applied at Leyden[2,5]: not very convincingly in the former paper, somewhat more so in the latter.

The three areas of sky listed in Table 1 were selected as showing comparatively large polarized components and each was observed regularly at transit over a period when there was a large variation to be expected in the total electron content of the ionosphere along the line of sight.

Table 1

Region	Centre of region	Magnitude of polarized component	Period of observation
a	α = 02h 54m δ = +67·5°	2·5 °K	Jan.–May 1962
b	α = 03h 54m δ = +67·5°	2 °K	Jan.–May 1962
c	α = 06h 07m δ = +45°	2 °K	Nov. 1961–April 1962

The instrument used was that described in reference 3 and the observations were made at transit in order that the spurious contributions due to galactic and ground radiation would remain unaltered throughout and only a true linearly polarized signal would be modified as the electron content of the ionosphere varied.

Most of the observations were made at night to avoid the problem of solar interference, but some were extended into the period just before sunset. The reception pattern of the aerial was known to be such that on these occasions any solar radiation was below the limits of detection.

The two regions at δ + 67·5° were observed at both upper and lower culmination. In the latter case the inclination of the geomagnetic field is nearly perpendicular to the line of sight and very little rotation would be expected.

The results obtained for each of the three areas are shown in Fig. 1, which gives the magnitude and direction of the electric vector of the apparent polarized radiation, the magnitude is expressed in terms of a 'polarization temperature' which is defined as the difference in aerial temperatures when the receiving system is rotated to receive first maximum then minimum radiation. The vectors shown are made up of (i) a genuine polarized signal; (ii) off-axis radiation from the ground; (iii) off-axis radiation from the Galaxy; (iv) instrumental effects.

Components (ii) and (iv) are independent of sidereal time and may therefore be determined by averaging the apparent polarization vector over a period of 12 h, since (i) and (iii) are likely to have an average close to zero over such a period. Component (iii) was computed from the known reception pattern and the distribution of brightness over the sky. It was found to be less than ½° K for each of the three regions and has been ignored.

The sum of (ii) and (iv) is shown in each of the figures by the vector S; the circle indicates the uncertainty in this vector. It can now be seen that the observed polarization vectors can be represented by the addition to S of a nearly constant vector the direction of which varies during the periods of observation; such a result is to be expected if the latter vector represents the true polarized signal (i) and the varying direction is related to the Faraday rotation in the ionosphere.

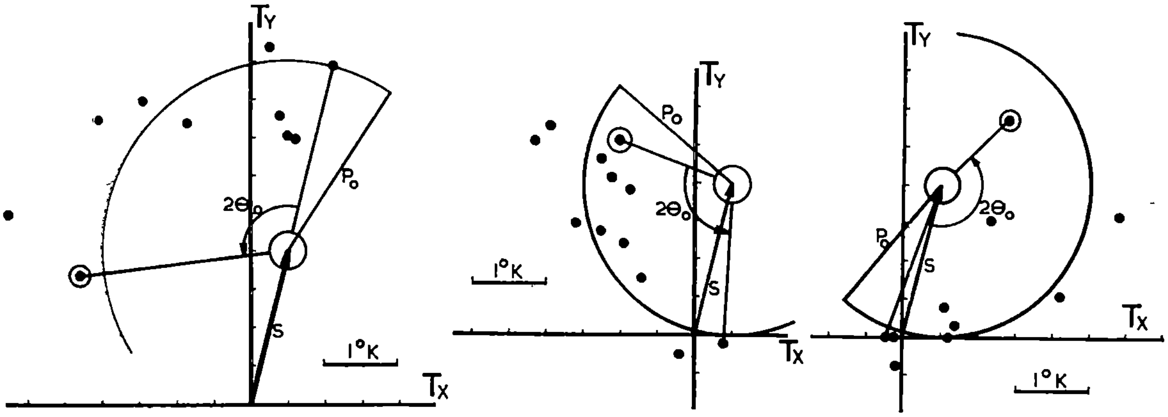
A comparison has therefore been made between the observed angle of this vector (θ_O) measured from an arbitrary zero and the predicted Faraday rotation angle (θ_P) computed from the ionospheric data for each night. θ_P is given[6] by the expression

$$\theta_P = \frac{A}{f^2} \int NB \cos\varphi \sec\chi \, dh \text{ degrees}$$

where $A = 1·4 \times 10^{-6}$, f = frequency in Mc/s, N = number of electrons per cm^3, B = magnetic induction in gauss, φ = angle between B and ray direction, χ = angle between zenith and ray direction, dh = element of height in cm, or approximately, with f = 408 Mc/s

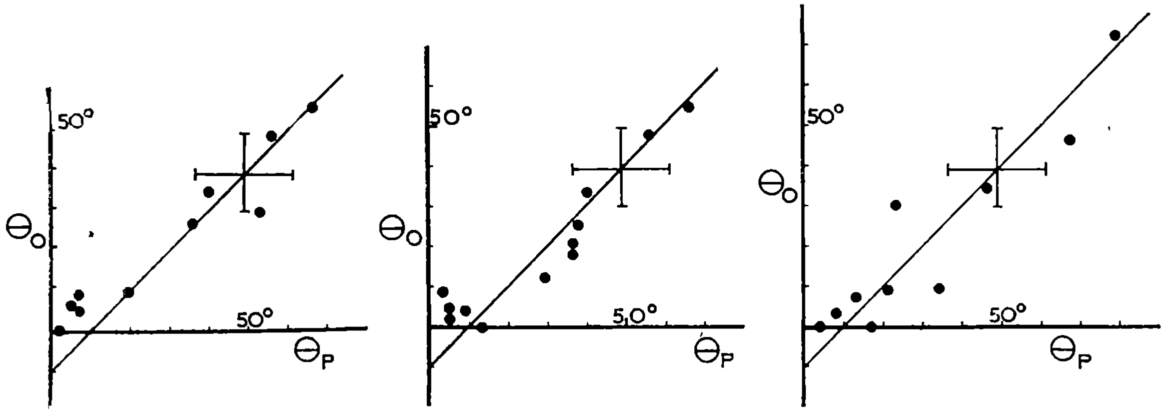
$$\theta_P = 8·1 \times 10^{-12}\, \overline{B \cos\varphi \sec\chi} \int N dh \text{ degrees}$$

The values of total electron content, $\int N dh$, have been derived by the application of ionospheric critical frequency data (f_0F_2) measured at Slough at the appropriate times to an ionospheric model[7] based on previous observations of total electron content[8-10].



a *b* *c*

Fig 1 Vector representation of observed polarization temperatures for the regions *a*, *b* and *c*



a *b* *c*

Fig 2 Comparison of the observed (θ_O) and predicted (θ_P) angles of the plane of vibration of the electric vector for the regions *a*, *b* and *c*

The results of plotting θ_O against θ_P for each of the three areas of sky are shown in Fig 2, the probable errors for an individual point are indicated

It can be seen that there is extremely good agreement between the observed and predicted rotation angles, this result and the relative constancy of the vectors P_0 in Fig 1 confirms the conclusion that P_0 must represent a true polarized component in the emission By projecting a 45° line drawn through the points in each of Figs 2*a*, *b* and *c* to $\theta_P = 0$ (corresponding to zero Faraday rotation) the position angle of the electric polarization vector outside the ionosphere can be found These directions are indicated on the sketch maps shown in Fig 3 It is noteworthy that the directions of the plane of vibration of the electric vector tend to be perpendicular to the galactic plane

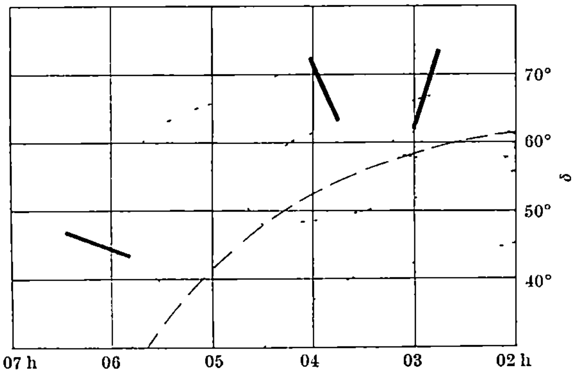


Fig 3 Sketch showing the direction of the plane of vibration of the electric vector for the regions *a*, *b* and *c* in relation to the galactic plane Background temperature contours at 404 Mc/s are also indicated

There is clearly the possibility that measurement of the direction of the plane of polarization, perhaps at some frequency other than 408 Mc/s, could be used as an alternative method to lunar radar and satellite observations for study of the variation of total electron content in the ionosphere

We thank Miss M E Davies for discussions, the Director of the Radio Research Station, Slough, for critical frequency data and the team at Leyden for the communication of their results prior to publication

LETTERS TO THE EDITOR

GEOPHYSICS

Half-life of Radiocarbon

AFTER full discussion of the new determinations[1-3] of the half-life of carbon-14, the Fifth Radiocarbon Dating Conference, meeting at Cambridge (see p 943 of this issue of *Nature*), adopted the following resolution

"We commend the three groups of research workers on their new determinations of the half-life of carbon-14, and upon their joint presentation of a figure to be used as a most probable value We agree that these results represent a significant improvement in our knowledge of this important physical constant, and that the mean of the values given, 5,730 ± 40 yr is now the best value available

"Inasmuch as further experiments may lead to an even more reliable result, we recommend, as a temporary expedient, that radiocarbon age results continue to be reported on the basis of the 'Libby half-life' 5,568 yr [4], used heretofore We anticipate that upon the conclusion of the experiments mentioned, the question of adopting a new procedure for reporting will be considered In the interim, published dates can be converted to the basis of the new half-life by multiplying them by 1 03, without appreciably altering the standard errors as quoted

"The delay in revising the basis of reporting will also allow time for evaluation of the carbon-14 content of dendrochronologically and historically dated samples "

A further action of the Conference was to confirm the practice of using A D 1950 as the reference year of 'zero age B P ' for purposes of reporting radiocarbon measurements

'Scale Frequency' of the Exosphere

WHISTLER measurements of nose frequency (f_n) and time delay at this frequency (t_n) give a f_n, t_n distribution well fitted by a 'gyrofrequency' model of electron density in the exosphere[1] one for which the electron density is everywhere proportional to the magnetic field strength or gyrofrequency (f_H) Since the electron density is directly proportional to the square of the plasma frequency (f_0) and uniquely determined by it we can express this model by the relation

$$f_0^2 = f_a f_H$$

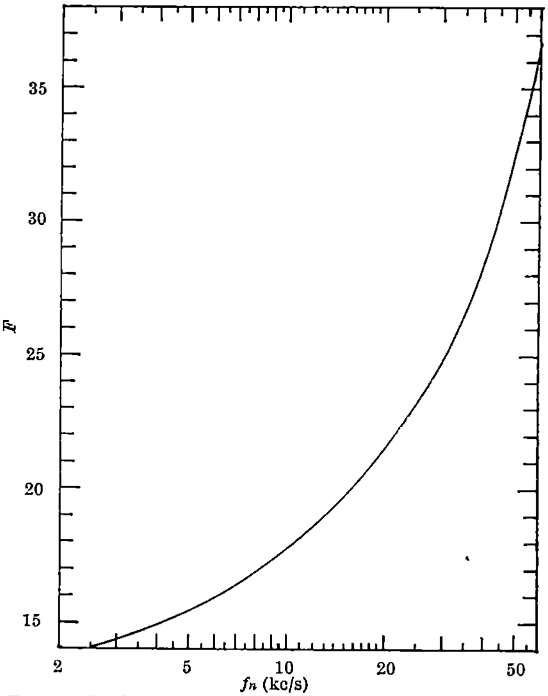

Fig 1 The function F for calculation of scale frequency from nose frequency and nose delay time

The constant of proportionality, f_a, has the dimensions of frequency and so might be called the 'scale frequency' of the exosphere It is typically around one megacycle per second (as deduced from Smith's work[1])

To the extent that the gyrofrequency model fits the real exosphere the scale-frequency is constant But the point I wish to make in this communication is that, regardless of this fit, the parameter, 'scale frequency', is a very useful one in exospheric studies. It is in the same form (frequency) as the other parameters (f_0, f_H, f) describing emission and propagation in the exosphere The low-frequency dispersion $D_0 = f^{1/2}t$ becomes $D_0 = s f_a^{1/2}$ where s is the half-length of the field line in light-time units (light-seconds) For f_a constant along a field line the nose whistler integral can be solved analytically[1] Since whistler data show that the scale frequency is at least quasi-constant then variations in space and time can be sensitively expressed by it This would be particularly useful in discussing magnetic disturbance effects

Scale frequencies are readily deduced from f_n, t_n data from nose whistlers A recent extension of whistler analysis[2] makes it possible to obtain f_n and t_n from perhaps all well-defined whistlers even when the nose is not directly observable In this work[2] it was shown that the nose frequency dispersion (D_n) is related to the low-frequency dispersion (D_0) as

$$D_n = 1\ 456\ D_0$$

Thus

$$t_n f_n^{1/2} = 1\ 456\, s f_a^{1/2}$$

Since the field line (and length s) is uniquely determined by the nose frequency, a function of f_n can be substituted for s Thus

$$f_a = F\,t_n^2\,f_n^{5/3}\ \mathrm{kc/s}$$

$$F = (1\ 456\,s f_n^{1/3})^{-2}$$

where t_n is measured in seconds, f_n in kc/s and the slowly varying function F is shown in Fig 1

It is interesting to note that a theoretical model[3] of electron density in the exosphere based on the premise that the electrons are controlled by the Earth's magnetic field rather than gravity gives a quasi-constant scale frequency Thus, this is largely a consequence of geomagnetic control of exospheres just as a quasi-constant scale height in the Earth's atmosphere is a consequence of gravity control

PHYSICS

Special Theory of Relativity

Two years ago I pointed out[1] what appears to be an inconsistency in the kinematical part of Einstein's special theory of relativity. I repeated this in a slightly different form in a volume published in December last[2]. No comment has been made on the former publication, either spontaneously or in response to individual requests, and in none of the many reviews of the latter has even an oblique attention to the criticism appeared In view of its profound and far-reaching consequences if it is valid there can be no justification for leaving a twice-published criticism without a published refutation if it is not

All experimental evidence yet obtained for the special theory is electromagnetic, and this would equally support Lorentz's earlier theory of an ether in which moving bodies are physically changed, and possibly other theories also No test of the kinematical requirements of Einstein's theory has ever been made—doubtless because it has so far been impossible to reach sufficiently high velocities except by the action of electromagnetic forces on charged particles The essence of the theory, however, lies in its kinematical requirements, and if these are falsified the whole theory collapses

Einstein's special theory is so intimately interwoven with modern nuclear physics that its disproof would have revolutionary theoretical effects, but there is another aspect of the matter which is, if not ultimately more important, at least practically more urgent Apart from this theory there is no reason to suppose (among other things) that the velocity of light, c, is unsurpassable, though if a higher velocity were reached in the laboratory the equations of the theory would necessarily register it as lower than c All velocities would be under-estimated and, with the increasingly high speeds now being attained, the consequences of this might be extremely serious In these circumstances the duty of publicly answering or accepting, at the earliest opportunity, a published criticism of the theory becomes compelling I therefore appeal for an answer or acceptance before further risks are taken

The alleged inconsistency lies in the fact that the argument used to prove that 'moving clocks run slow' (with which all the kinematical implications of the theory are bound up) proves, with exactly the same validity, that moving clocks run fast Both cannot be right, so the basis of the theory must be faulty To show this in the most fundamental manner possible, and at the same time to make the task of refutation as simple and direct as possible, I quote here the passage from Einstein's original paper[3] which purports to prove that moving clocks run slow, together with a parallel passage which similarly proves the opposite

In the former passage two clocks are introduced, one of which is at rest in an arbitrarily chosen 'stationary' co-ordinate system, K (co-ordinates x, y, z, t), while the other is at rest in a 'moving' co-ordinate system, k (co-ordinates ξ, η, ζ, τ) The transformation equation between the time co-ordinates has previously been given in the algebraically equivalent forms

$$\left.\begin{aligned}\tau &= \beta(t - vx/c^2)\\ t &= \beta(\tau + v\xi/c^2)\end{aligned}\right\}$$

where $\beta = 1/\sqrt{(1 - v^2/c^2)}$

Here is the passage from Einstein's paper "We imagine one of the clocks which are qualified to mark the time t when at rest relatively to the stationary system, and the time τ when at rest relatively to the moving system, to be located at the origin of the co-ordinates of k, and so adjusted that it marks the time τ What is the rate of this clock, when viewed from the stationary system ?

"Between the quantities x, t, and τ, which refer to the position of the clock, we have, evidently, $x = vt$ and

$$\tau = \frac{1}{\sqrt{(1 - v^2/c^2)}}\,(t - vx/c^2)$$

Therefore

$$\tau = t\sqrt{(1 - v^2/c^2)} = t - (1 - \sqrt{(1 - v^2/c^2)})t$$

whence it follows that the time marked by the clock (viewed in the stationary system) is slow by $1 - \sqrt{(1 - v^2/c^2)}$ seconds per second, or—neglecting magnitudes of fourth and higher order—by $\frac{1}{2}v^2/c^2$ "

And here is the parallel passage, leading to the opposite conclusion We imagine one of the clocks which are qualified to mark the time t when at rest relatively to the stationary system, and the time τ when at rest relatively to the moving system, to be located at the origin of the co-ordinates of k, and so adjusted that it marks the time τ What is the rate of this clock, when viewed from the stationary system ?

Between the quantities ξ, τ, and t, which refer to the position of the (other) clock, we have, evidently, $\xi = -v\tau$ and

$$t = \frac{1}{\sqrt{(1 - v^2/c^2)}}\,(\tau + v\xi/c^2)$$

Therefore

$$t = \tau\sqrt{(1 - v^2/c^2)} = \tau - (1 - \sqrt{(1 - v^2/c^2)})\tau$$

whence it follows that the time marked by the clock (viewed in the stationary system) is fast by $1 - \sqrt{(1 - v^2/c^2)}$ seconds per second, or—neglecting magnitudes of fourth and higher order—by $\frac{1}{2}v^2/c^2$

I should point out that this contradiction has nothing to do with the mere paradox that, if there is an observer with either clock, he will find the other's clock running slower than his own There are no such observers, and if there were they could be ignored The situation, as presented by Einstein, is entirely objective All the necessary readings could be recorded impersonally and the records studied later Nor is it a matter of change of co-ordinate system There is no such change the same clock (A) is chosen as the 'stationary' clock, and the same clock (B) as the 'moving' clock, in both cases, and every symbol has exactly the same meaning in both cases The conclusion of the first passage is that each reading of B is behind the corresponding reading of A, and that of the second passage is that each reading of A is behind the corresponding reading of B Thus, if $\sqrt{(1 - v^2/c^2)} = \frac{1}{2}$, and $t = 12$, Einstein's equation gives $\tau = 6$, and when $\tau = 6$ the other equation gives $t = 3$ Hence, when B reads 6, A read both 12 and 3 That is a contradiction

To avoid this outcome it must be explained not why the two cases are different—that is obvious—but *why, consistently with the theory, the former result must be accepted as true while the latter must be rejected as false*

Sizing of the Fall-Out at Vienna

DURING December 22, 1961–January 8, 1962, the occurring aerosol at Vienna was sampled for 403 5 hr continuously on filter paper *F* (Schleicher und Schull chromatographierpapier 2043 *Mgl*) by a Goetz aerosol spectrometer *AS*[1] at the site of the First Physics Institute of the University (window on the second floor) The spectrometer effects the quantitative separation and size selective deposition of the airborne particulate matter The deposit pattern yields the size distribution The operating conditions of the spectrometer for this run were 10,000 r p m and 40 mil limiting orifices, that is, the spectrometer did sample all the airborne particles with Stokes's diameters δ between 0 3μ and 5μ at a rate of 3 0 l /min (total volume of the sample 72 6 m³)

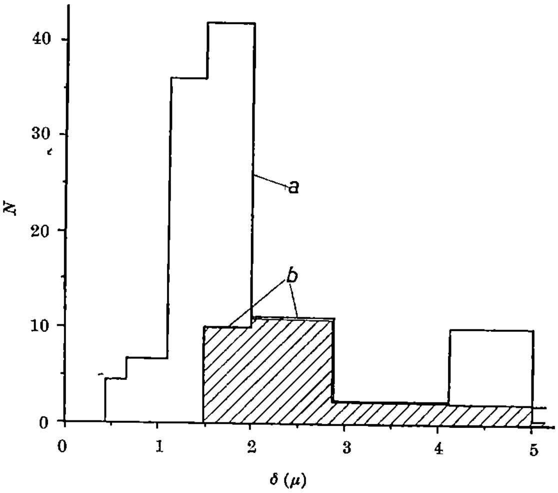

Fig 1 Size distribution of fall-out particles *N*, Number of particles in the sample of 72 6 m³ for the diameter-range 1μ versus *δ*, Stokes-diameter Curve *a*, Each particle bearing an activity 0 5 × 10^{-12} c , curve *b*, each particle bearing an activity between 0 5 and 0 07 × 10^{-12} c

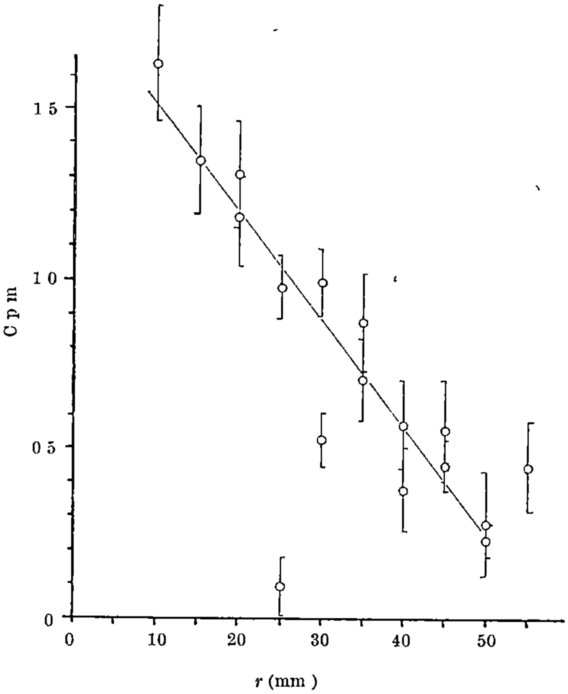

Fig 2 β-activities at February 22, for the sample of 72 6 m³ in c p m for the disks of 6-mm diameter versus position parameter *r* in mm

After the run the filter paper was removed from the spectrometer and two autoradiographs *m* and *n* were taken on Kodak X-ray blue brand, *m* 20 hr and *n* 168 hr exposure-time, both developed in 'Ixal' automatic (Daniel, Wien) for 4 min at 18° C The autoradiographs showed all the single particles bearing a β-activity larger than approximately 0 5 × 10^{-12} C (potassium-40 equiv) for *m* (ref 2) and 0 07 × 10^{-12} C for *n* The first value was estimated by measuring the activity of single particles, the second one by comparing the exposure-times On the autoradiograph *m*, 24, and on *n*, 102 active particles were observed, but, on *m*, 20, and on *n*, 81 particles could be used only for calculating the size distributions given in Fig 1

The size distributions of Fig 1 should be considered as estimates, for the number of observed particles was rather small (The sizings were based on statistics of the deposition loci of the particles)

About two months later the sample was further investigated Disks of 6-mm diameter were cut out of the filter paper at given positions—position parameter *r*—avoiding particles shown at the autoradiographs so far as possible The position parameter *r* is the distance between the point on the filter paper under consideration and the origin of the Archimedian spirals defining the deposit pattern of the spectrometer minus a constant It proved to be more convenient than the spiral-length *L* used in former work[3-6] These disks were mounted at the centre of the planchets of the Tracerlab low-background-β-counter *CE*14 The resulting β-activity in c p m was measured and the activity of the samples calculated

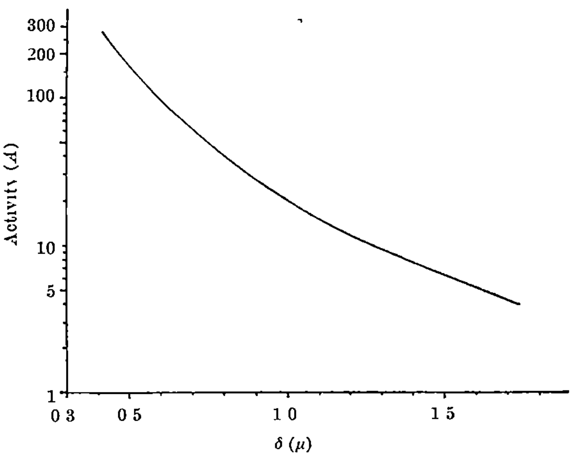

Fig 3 Distribution of the β-activity A versus Stokes diameter δ

for the reference date February 22, 1962 (Time necessary for counting one single disk up to 48 hr , several disks were counted twice for estimating the decay during the counting period) Fig 2 shows the β-activity versus position parameter The range given to each activity in Fig 2 corresponds to 1 96σ (σ = standard deviation), this range was calculated from counts only, errors from sampling as well as cutting and mounting the disks were not considered

From this curve the distribution of the β-activities versus Stokes-diameter (Fig 3) was calculated in the usual manner[4] The activity A is given in c p m for the whole sample of 72 6 m[3] and Stokes-diameter intervals of 1μ

Fig 1 and Fig 3 yield the following information the β-activity was mainly attached to particles of Stokes-diameters smaller than about 0 7μ In most of the cases one single particle does not bear enough activity to show up in autoradiographs unless the particle is larger than 1μ Only a relatively small activity seemed to be attached to particles of Stokes-diameters of 0 7–1 0μ

Experimental Evidence for the Concept of the Displacement Spike

THE mechanisms by which fast, heavy, and charged particles lose energy to crystalline matter are generally explained in terms of either thermal[1] or displacement[2] spikes The mere fact, however, that a majority of the energy is dissipated in the excitation of orbital electrons and the creation of a thermal spike does not necessarily imply that the resulting radiation damage is so formed In uranium, for example, the existence of a continuous band of energy-levels above the Fermi surface permits a temporary excitation of the valence electrons, since these may fall back to their original levels and so deliver their energy to the lattice as heat For such cases, the bulk of the remanent radiation damage may well derive from the Coulomb interactions which the particle makes with lattice atoms in the crystal Brinkman[3] has shown, by use of the atomic interaction potential

$$V(r) = (AZ_1Z_2e^2)\frac{\exp(-Br)}{1-\exp(-Ar)}$$

which approximates to a Coulomb repulsion for close interactions and a Born-Mayer exponential repulsion for large separations, that, for a light uranium fission fragment travelling through uranium, atomic dis-

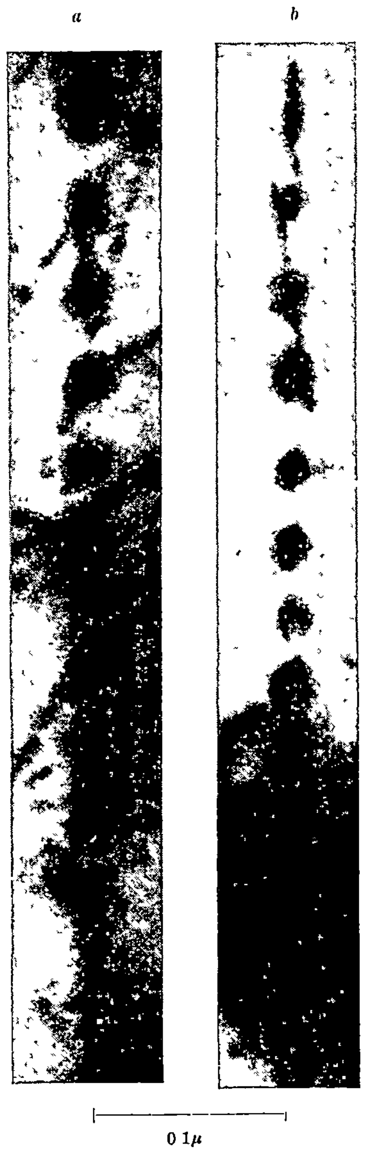

Fig 1 *a*, Electron micrograph showing the discontinuous nature of fission fragment tracks in molybdenum disulphide, *b*, electron micrograph of a fission fragment track in molybdenum disulphide The segments are resolvable as dark contrast loops placements are produced every 40 Å on the average Occasionally the displacement produces a highly energetic ($\sim 10^5$ eV) primary knock-on which proceeds to lose energy by hard-sphere collisions In such cases a displacement spike can be formed Atoms are driven into the surrounding lattice to occupy interstitial positions on a closed shell which surrounds a core of vacant lattice sites

A number of electron microscopists have examined the tracks which fission fragments produce in crystalline matter, and it has generally been concluded that thermal spikes are responsible for the observed effects Experimental evidence for the concept of the displacement spike has so far been equivocal In crystals of molybdenum disulphide, however, the observation of intermittent dark contrast tracks suggests a discontinuous release of energy by the fission particle[4] There can be no doubt that some of the intermittent contrast effects are due to dynamic diffraction effects at inclined continuous and linear regions of strain Such phenomena are similar to those seen at inclined dislocation lines in metal foils and can be partially explained by an application of the kinematic theory of electron diffraction In the majority of cases, however, the contrast effects survive a tilting of the specimen about an axis perpendicular to the electron beam and these are therefore real in nature An example is given in Fig 1*a* It will be observed that the separation between the segments gradually decreases In some of the tracks the segments are clearly resolvable as dark contrast loops (Fig 1*b*) and there is evidence[4] that these are closed dislocation lines

It is possible to explain these observations by adopting the ideas of Brinkman[3] If it be assumed that the energy which is delivered to the electrons in molybdenum disulphide is spread throughout the lattice as heat (the electrons are highly mobile between molecular layers) then the damage-creating mechanism is that of displacement As the particle loses energy the separation between successive displacement spikes decreases until a merging results in the formation of a continuous track For isolated displacement spikes the configuration is unstable and collapse can result in the formation of a closed vacancy dislocation loop[5] In the continuous region a dislocation dipole[6] or a long dislocation loop can be formed —there is basically no difference between these two types of extended defect

It may be concluded that the concept of the displacement spike is useful for visualizing the dynamic processes which occur when displacement cascades are produced by heavy particles The energy which is communicated to the electrons, however, may result in the initiation of a thermal spike, and this may be the dominant mechanism of damage creation in other types of crystal[6]

I thank Dr F P Bowden for his advice

ENGINEERING

A 5-Mc/s Klystron Amplifier using Positive Ions

AN experimental investigation of the principles of microwave klystrons is rendered difficult by the inherently high operating frequencies at which it is not feasible to measure such quantities as input and output voltages An important parameter in the klystron is the length of the drift space In the normal operating range this is usually less than 1 cm It is therefore difficult to carry out quantitative experiments in which the drift-length is varied The drift-length depends on the transit time of the electrons and its relation to the high-frequency period Thus lowering the operating frequency gives longer drift-lengths Cullen and Stephenson constructed a special demountable klystron to operate at a frequency of 300 Mc/s, in which the optimum drift-length was about 5 cm and it was fairly easy to investigate the effect on performance of varying this length Voltage measurement at 300 Mc/s still presented some problems

By using beams of positive ions instead of electrons, transit times are changed in the ratio $\sqrt{(m_i/m_e)}$ where m_i, m_e are the masses of the ion and the electron respectively Thus it becomes possible to investigate velocity modulation effects at much lower frequencies Using argon ions we have constructed a klystron amplifier to operate at a frequency of 5 Mc/s Voltage gains up to five times have been obtained The optimum drift-length is about 5 cm with currents of 3 mA and accelerating voltages of 2–4 kV Preliminary investigations have shown that the performance gives good quantitative agreement with the small signal space-charge wave theory of Ramo and Hahn[2,3] It appears therefore that the positive ion klystron is a good analogue of the microwave klystron and the possibility arises of investigating microwave electronic problems at low frequencies, where measuring techniques are relatively simple

Thermocouple Electric Motors

FURTHER to the recent publications[1,2] on the subject of electrostatic motors running at high voltage and low current, I gave consideration to design possibilities of a thermocouple-driven motor operating at a few mV but a heavy current

A pilot model was made and ran satisfactorily, due to the voltage drop of normal brush gear being too high, mercury commutation was tried This motor ran well, but considerable splashing of mercury occurred which was unsafe from the health angle A totally enclosed design was adopted (Fig 1) The motor was powered by a single massive thermocouple of iron-constantan

The main particulars are (all resistances in μohms)

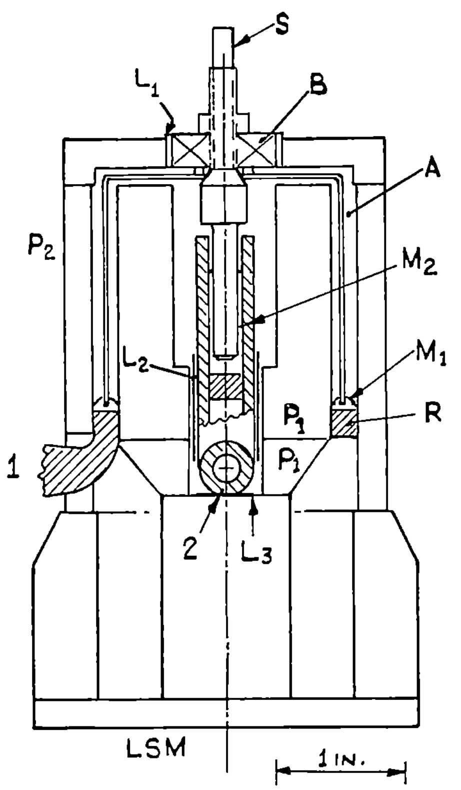

Fig 1 Schematic section of thermocouple motor P_1P_2, Soft iron concentric pole pieces, *LSM*, loud speaker magnet, *A*, copper ring armature 0 03 in thick carried by copper shaft *S* running in ball-bearing *B*, rotates in annular air-gap, 1,2, connexion points for iron and constantan limbs of thermocouple (not shown), M_1, annular mercury contact ring for *A*, resting on copper ring *R* and connected to 1, M_2, mercury pool affording connexion between *S* and 2, L_1,L_2,L_3, insulating liners Vertical anti-eddy current slots are provided in the armature *A*, slots not shown Thermo element sizes, constantan, one piece *c* 0 16 in thick by 1 in wide by *c* 2 in long, iron, 4 rods in parallel, *c* 0 25 in diam × *c* 4 2 in long Water cooling is incorporated but omitted from the drawing for clarity

Motor total copper resistance, *c* 125, mercury contacts, *c* 5, total, 130

Thermocouple total iron resistance, *c* 130, constantan resistance, *c* 390, total, 520

Running the motor just starts to run comfortably at about 100° C hot junction temperature, say 4 mV With a total circuit resistance of 650 μohms the current would be a little over 6 amp, representing frictional losses of about 0 025 W

Output with a hot junction of 700–800° C, $E = c$ 30 mV, $I = c$ 46 5 amp, power = 1 4 W

Improvement it would balance the design if the couple resistance were lowered to equal that of the motor 4 thermocouples in parallel would do this At 700°–800° C, as before, we might expect $E = c$ 30 mV, $I = c$ 115 amp, power = a little less than 4½ W

A test stand incorporating a parabolic mirror is being made It is hoped to make some trials using solar energy as the heating medium, when suitable weather comes along

X-ray Evidence for Cement–Clay Interaction

LARGE quantities of Portland cement are used annually for the stabilization of soils for roads, airfields, and other engineering works While the improvement in engineering properties effected by cement treatment is believed due mainly to the hardening of cement, reactions between hydrating cement and clays leading to the formation of additional cementitious material have been suggested[1]

Several factors would appear to be significant in the formulation of a hypothesis for cement–clay interaction

(1) Hydrating cement is a partly crystalline, multiphase, alkaline system containing calcium hydroxide, calcium silicate hydrates, and hydrating aluminates, and lime is released during hydration[2]

(2) Silica and alumina may be dissolved from clay minerals by alkalis or calcium hydroxide[3]

(3) Ion exchange and flocculation occur rapidly when lime is mixed with clay minerals in the presence of water Excess lime may react with the mineral through pozzolan-type reactions, forming products that are initially amorphous but may later become crystalline X-ray investigations have indicated a destruction of montmorillonite mineral structure and moderate attack on kaolinite in the presence of calcium hydroxide[4]

Consideration of these factors suggests that in hardening clay–cement mixtures, hydration and hydrolysis of the cement could be regarded as primary reactions Usual cement hydration products would form, the *p*H of the pore solution will increase and fresh, highly reactive lime would be generated The clay phase will enter into secondary processes Calcium ions produced by cement hydration convert the clay to the calcium form and cause flocculation Calcium hydroxide initiates attack of the clay particles Silica and alumina dissolved in the high *p*H environment could combine with calcium and form additional cementitious material which would form on or near the surface of clay particles and tend to 'glue' them at points of contact Even stronger bonds would develop between hydrating cement grains and the clay particles coating these grains The resultant structure would consist of a high-strength cement–clay skeleton and clay matrix Units of the skeleton would contain a core of hydrated cement gel to which layers of degraded clay particles are bonded Less-decomposed clay would be trapped in the intercellular space

Kaolinite – cement and montmorillonite – cement specimens containing 15 and 30 per cent cement by weight were prepared by kneading compaction and cured for different periods at 60° C in a 100 per cent relative humidity atmosphere Compaction water content was slightly greater than optimum for the compactive effort used Unconfined compression tests on specimens soaked in water for 24 h after curing periods of 1, 7, 28, and 84 days gave strengths several times those for unsoaked, untreated specimens indicating very effective stabilization X-ray diffraction traces were obtained using copper radiation on samples of powder prepared from specimens cured for similar times

X-ray spectra for hydrating neat cement pastes were dominated by the formation of calcium hydroxide lines at 1 92, 2 62, and 4 93 Å, having intensities that increase with curing time The formation of calcium silicate hydrate (CSH) was observed

Tests on kaolinite–cement mixtures revealed no calcium hydroxide lines except in the case of kaolinite plus 30 per cent cement cured for one day. On the other hand, 4·93 and 2·62 Å lines were easily identified on traces for kaolinite blended with 30 per cent of ground cement that had been hydrated for 3 months. This indicates that the absence of calcium hydroxide lines is not due to masking effects by kaolinite. But since the compression tests indicate large strength increases with curing time and calcium hydroxide was identified in the high cement content specimen cured for one day, it would appear that the cement hydrated normally and formed calcium hydroxide. Since calcium hydroxide is not present in a crystalline form in the kaolinite–cement, it must be present either in an amorphous form or used up by a secondary process. Some weakening of kaolinite reflexions was noted at the higher cement content, suggesting an attack on the kaolinite structure by cement hydration products.

No calcium hydroxide lines were noted on the diffraction patterns for montmorillonite–cement. However, as in the case of kaolinite–cement, calcium hydroxide peaks were pronounced for a mixture of montmorillonite plus 30 per cent ground hydrated cement, indicating that 'dilution' of cement by montmorillonite could not have masked the appearance of calcium hydroxide lines. At 15 per cent cement content the 14 Å montmorillonite basal reflexion increased in height and sharpness during the longer curing periods. A similar intensification of montmorillonite basal reflexions caused by a small amount of lime added was noted by Eades and Grim[4]. At a cement content of 30 per cent the montmorillonite reflexions weakened with increased curing time suggesting major structural breakdown.

Chemical analyses performed in conjunction with the X-ray tests indicated continual decreases in *p*H, free calcium hydroxide content, free electrolyte content, and extractable calcium content with curing time. Values of these quantities were consistently lower than values computed by proportion on the basis of measured values for hydrating neat cement pastes. These results also support the existence of secondary processes involving the lime generated by the hydrating cement and the clay.

New lines of low intensity were observed in some X-ray patterns for specimens containing 30 per cent cement at long curing times. This suggests the formation of new crystalline reaction products. These products have not, as yet, been positively identified.

METALLURGY

Yield Point in Mild Steel

NUMEROUS investigations of the factors controlling the lower yield point have shown that the lower yield point (σ_{LYP}) varies with grain size (d) according to the equation

$$\sigma_{LYP} = \sigma_0 + k_y d^{-1/2}$$

Several investigators have shown that k_y is independent of composition and does not depend to any great extent on temperature. The main source of temperature dependence and of composition dependence arises from the factor σ_0, which may be regarded as containing the frictional effects opposing the motion of dislocations during the Luder's extension.

Cracknell and Petch[1] investigated the frictional effects of carbon and nitrogen on σ_0. Their results indicate an equation of the type

$$\sigma_{LYP} = \sigma' + k'(C+N) + k_y d^{-1/2}$$

Heslop and Petch[2] examined the effect of manganese and derived a similar formula to explain their results

$$\sigma_{LYP} = \sigma'' + k''(Mn) + k_y d^{-1/2}$$

In both cases, k_y was relatively unaffected by composition variation.

In the course of a multiple regression analysis of the properties of mild steel, the regression coefficients between the lower yield strength and the composition variations for manganese and silicon were determined as being 2·1 t.s.i. and 2·7 t.s.i. respectively per 1 atomic per cent of solute. In a similar investigation to that carried out by Cracknell and Petch, it was found that the corresponding regression coefficient was approximately 90 t.s.i. for carbon and/or nitrogen. Once again it was found that k_y was uninfluenced by variations in composition and that these elements contribute to the yield strength through the frictional component of σ_0.

The regression coefficients are plotted in Fig. 1 as a function of the distortion produced in binary iron alloys per 1 atomic per cent of solute. The data of Heslop and Petch[2] for manganese and of Cracknell and Petch[1] for carbon and/or nitrogen are included in Fig. 1. A logarithmic scale has been used for convenience, the slope of the line was assumed to be unity to conform with a straight-line relationship on a linear scale graph.

Although Fig. 1 shows a relationship between the increase in yield strength per 1 atomic per cent solute versus the mean lattice distortion, it must not be inferred that this lattice distortion (as measured

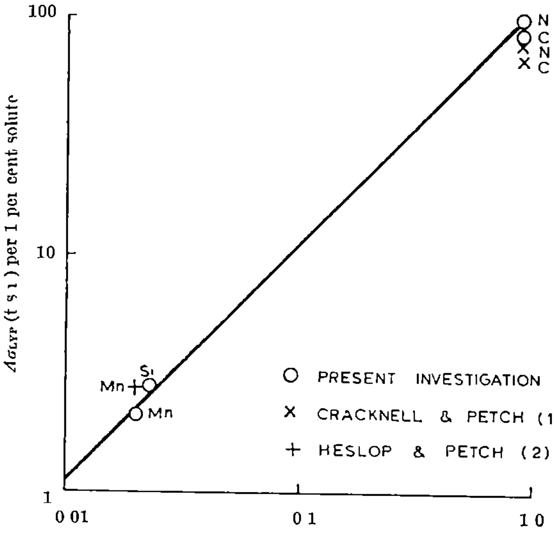

Fig. 1. Change in lower yield strength versus lattice distortion per 1 atomic per cent

by the increase or decrease of mean lattice parameter) is the controlling factor. If this were the case then silicon, which contracts the lattice, should counteract the effect of manganese, which expands the lattice. This is not so, for the effect of these elements is additive. The average dilation of the lattice is merely an average measure of the local distortion around each solute atom, and hence a measure of the binding energy between dislocation and solute atom[3].

One of the difficulties associated with this model is the fact that carbon and nitrogen give rise to an anisotropic strain and produce localized tetragonality, whereas substitutional elements such as silicon and manganese produce an isotropic strain. Nevertheless, it is interesting to observe that the change in yield strength, or more particularly, the change in the frictional contribution to σ_0, is directly proportional to the concentration of solute, at least in dilute solutions, and that the ratio of the change in lower yield point to the lattice distortion is approximately the same for both substitutional and interstitial solutes.

I thank Dr. F. H. Saniter for permission to publish this communication.

Flow of Cadmium under Very Small Stresses

AT room temperature cadmium is very much more resistant to plastic deformation than lead, as can easily be proved by trying to bend permanently by hand rods or bars of the two metals, of like dimensions. For example, a bar of cadmium 18 cm. long by 1.5 by 0.6 cm. cannot be perceptively bent by hand with ordinary effort, while a similar bar of lead bends as much as is desired extremely easily.

However, under very small stresses applied for a long time, which have no effect on lead, cadmium yields markedly. This is, perhaps, most strikingly shown by arranging a bar as a horizontal cantilever so that it is subject to a bending movement due to gravity alone. The photograph shows a bar of lead and a bar of cadmium, of the dimensions given above, which were clamped at the right over a distance of 3 cm. and left for 14 weeks at room temperature. There is no perceptible distortion of the lead, but the cadmium has yielded in the manner shown and is still yielding.

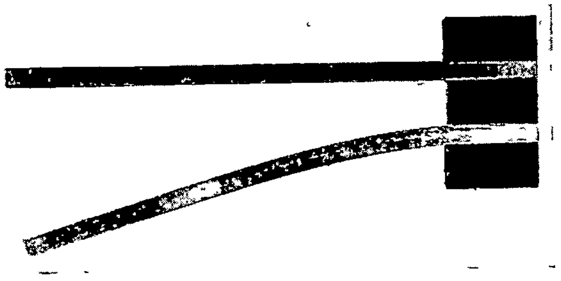

Fig. 1. Lead (above) and cadmium (below) 14 weeks under gravity

A sixpence left between two horizontal plates of cadmium, the upper of which supported a weight of 55 kgm., made little indentation in 20 hr., but in the course of 6 weeks effected a clean cut intaglio of both sides of the coin.

Dr. D. Aboav, who is working on the creep of cadmium under simple shear by the method already described[1], has found flow at a rate of 4×10^{-3} per cent shear strain per hour under a shear stress of 100 gm. wt./mm.^{2} and has detected flow at stresses as low as 10 gm. wt./mm.^{2}. The magnitude and the type of flow, whether $t^{1/3}$, linear with time or compounded of both, is intimately connected with grain size.

Zinc is being investigated for the effect.

CHEMISTRY

Viscosity Dependence of Unimolecular Conversion from the Triplet State

THE dependence of triplet state lifetimes on solvent viscosity noted in the first studies of triplet states in solution[1] is due, in part, to quenching by trace impurities not yet identified[2,3]. Hoffman and Porter[3] showed that, in certain molecules containing heavy atom substituents, the radiationless transition probability is increased to the point where it predominates over these trivial quenching processes and they conclude that, under these conditions, the measured lifetime corresponds to a true unimolecular radiationless conversion to the ground-state.

In the particular case of 9,10-dibromoanthracene, where quenching effects were negligible, the unimolecular decay constant was found to be independent of solvent viscosity in the range 1 (*cyclo*hexane) to 170 (liquid paraffin) centipoise at room temperature. On the other hand there was evidence that the

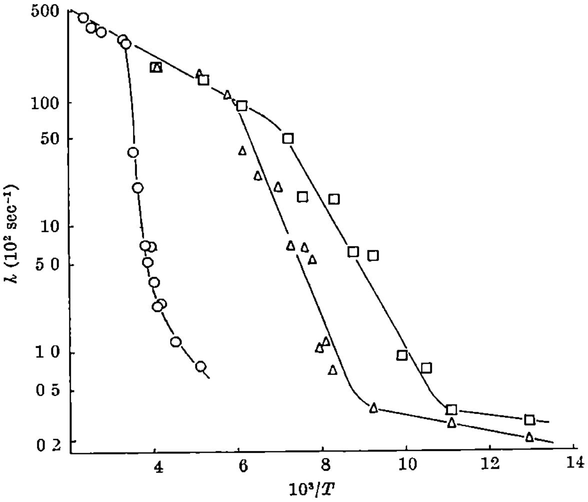

Fig. 1. Plot of logarithm of first-order rate-constant for triplet decay of 9,10-dibromoanthracene against reciprocal of absolute temperature. Solvents: propylene glycol (○), 3-methyl pentane (△), isopentane (□)

rate of decay is considerably reduced in very viscous solvents at low temperatures, and the relative importance of viscosity and temperature on this phenomenon remained unresolved We have now determined the rate constants of first-order triplet decay of 9,10-dibromoanthracene over a wide temperature range (+ 150° to − 196° C) in three solvents of different viscosity Our findings, though rather unexpected, resolve the apparently contradictory observations already referred to

In Fig 1 the logarithm of the rate constant of triplet decay of 9,10-dibromoanthracene in three solvents, propylene glycol, 3-methyl pentane and isopentane, is plotted against the reciprocal of the absolute temperature with which the viscosity increases, though not necessarily in a linear manner Each of the curves exhibits three characteristic regions

(1) A low-viscosity region where the rate constant, at a given temperature, is the same in all three solvents as well as in other solvents investigated, and is therefore independent of viscosity The temperature dependence of rate in this region corresponds to an activation energy of 0 8 kcal/mole in all three solvents

(2) A high-viscosity region where the rate constant is again nearly independent of solvent viscosity and has a zero or very small temperature coefficient (It was not possible to extend this region to lower viscosities in propylene glycol owing to cracking of the glass)

(3) An intermediate region where the rate decreases rapidly with increasing viscosity from limiting value (1) to (2) This region appears in a different temperature range for the three solvents and lies close to the melting point (It should be pointed out that below the melting point all these experiments are made in supercooled liquids and not in crystalline media) The plots are approximately linear in this region and correspond to activation energies of 16 2, 3 8 and 2 7 kcal/mole in propylene glycol, 3 methyl pentane and isopentane respectively

We have measured the viscosity of propylene glycol over the same temperature-range and find that log viscosity is a nearly linear function of the reciprocal absolute temperature with no discontinuities corresponding to those in Fig 1 The activation energy for viscous flow is 15 9 kcal and the viscosity at which the rate constant begins to fall from region 1 is approximately 50 cP

Investigations of other solutes in isopentane solution by Hilpern and Porter[4] also show two distinct regions of triplet decay-rate at high and low viscosity as well as the viscosity dependent quenching processes which are present in some cases In a recent publication[5] Jackson and Livingston mentioned some preliminary measurements on anthracene in glycerol which might be interpreted in a similar way

In seeking an explanation of the two processes of triplet decay, it is necessary to consider carefully the possibility that a further quenching process is operative This would require a quencher the reaction of which became kinetically encounter (diffusion) controlled at a viscosity of about 50 centipoise in propylene glycol This implies a quenching rate constant of 1 3 × 10^8 l $mole^{-1}$ sec^{-1} and a quencher concentration of 2 × 10^{-4} mole/l We have found that the first-order rate-constant is independent of solute concentration in region 1 from 2 × 10^{-4} to 2 × 10^{-6} mole/l and since it is also accurately independent of solvent in six different solvents investigated, quenching processes of this kind seem to be definitely eliminated We conclude that there are two distinct mechanisms of unimolecular decay of the triplet state which predominate in regions of high and low viscosity respectively

Possible ways in which viscosity might affect the rate of radiationless conversion from the triplet state were recently discussed[6] and will not be repeated here Our results show that the influence of viscosity is to eliminate one process completely over a relatively small range of viscosities and that outside the region viscosity effects are negligible The only molecular parameter which is known to change drastically in this region is the relaxation time of Brownian rotation If this is indeed the significant parameter the low-viscosity rate-constant may correspond to a radiationless transition in which coupling of molecular rotation with electronic motion is of prime importance in determining the transition moment

Reaction of Elementary Carbon and Hydrogen in High-Frequency Discharge

IT has been recently reported[1] that hydrogen atoms produced by the action of microwave discharge on hydrogen gas can react with solid carbon only when the latter is in the plasma Similar observations have been made independently in this laboratory. The results of these and subsequent experiments have led to a possible mechanism for the participation of carbon in such a system

When a spectroscopically pure graphite rod, 3 mm long, 3 mm diam , was placed in a silica tube at the centre of the plasma of purified hydrogen gas, methane, acetylene, and to a much smaller extent, ethane and ethylene, were found among the gaseous hydrocarbon products, as analysed by gas chromatography The results of a number of experiments in which the hydrogen flow has been varied are given in Table 1

Table 1

H_2 flow µmole/min	Pressure mm Hg	Rate of production of hydrocarbon gas µmole/min				
		CH_4	C_2H_2	C_2H_4	C_2H_6	CH_4/C_2H_2
210	0 47	1 50	0 16	0 02	0 02	9 4
125	0 47	1 24	0 21	0 02	0 01	5 9
35	0 47	0 67	0 45	0 02	0 02	1 5

Microwave power, 85 W (frequency, 2,540 Mc/s), length of graphite rod, 1 cm

The overall temperature of carbon in this system was about 700° C as indicated from its faint glow in the discharge When the location of the carbon source was systematically varied, it was found that the total amount of products decreased rapidly as the carbon was moved away from the centre of the plasma This is in contrast to the reactivity of oxygen atoms toward elementary carbon, since the latter is attacked even when far removed from the plasma region

When hydrogen was replaced by a stream of helium gas which had previously been purified by repeated passage through a series of charcoal and molecular sieve traps maintained at − 196° C, it was found that in certain conditions (pressure, 0 7 mm mercury, flow, 10 ml /min, MW power, 42 W) with the graphite rod still at the centre of the field, large deposits of carbon were formed on the silica tube in the shape of rings in the direction of pumping These deposits could be removed when the pressure of the gas was increased and the field moved so as to cover them Similar ring deposits could also be found when a stream of air replaced helium under the same experimental conditions However, no such deposits were noted when hydrogen gas was flowing through the tube (Operation of the discharge with hydrogen gas for long periods resulted in the formation of yellow deposits on the walls of the tube These were presumably high molecular weight hydrocarbon products) These experiments indicate that a mechanism for evaporating carbon from the graphite rod at about 700° C is operative in this system and that the reaction with hydrogen may be wholly due to gaseous carbon which is absent when the graphite is outside the plasma The appearance of methane as the major product indicates that a significant portion of the gaseous carbon is monatomic Acetylene could arise either from the reaction of C_2-species with hydrogen or by the attack of atomic carbon on the newly formed methane That the latter reaction is indeed significant is borne out by the fact that the relative abundance of acetylene is increased when hydrogen gas flow is reduced (Table 1) This is in conformity with the presence of carbon atoms as they are expected to undergo C—H bond insertion reaction with methane to form acetylene[2]

Two possible mechanisms for the production of gaseous carbon in this system appear plausible The first involves collisions of energetic positive ions (for example, He^+) with the surface of the carbon to produce sputtering[3] This process is well known in the production of d -c arcs where the cathode carbon rod is consumed Positive ions in the bulk of the plasma in my system are not expected to acquire the necessary energy for sputtering from the relatively weak and rapidly oscillating fields which are used However, it is expected that the ions which lie within one mean free-path of the surface of the carbon be accelerated through high fields which must appear at pointed regions on the surface of the conductor The second mechanism involves inelastic collisions of energetic electrons with the surface of the carbon, imparting sufficient energy to produce localized heating and evaporation

Contributions of triplet atoms and molecules for sputtering collisions in the case of helium gas must be small, since these species are relatively long-lived[4] and therefore are expected to be available for such a process outside the plasma They could also be formed outside the discharge zone by resonance light absorption of the helium gas However, no sputtering is observed for any of the above gases when the graphite rod is outside the microwave field

Baun and Fischer[5] have recently reported the formation of positive ions of carbon up to C_{28}^+ from a high-frequency spark between graphite electrodes The relative abundance of these species, measured by mass spectrometer, drops sharply as the mass increases. In the electrodeless discharge used in my system, there is no such direct evidence concerning the nature of the carbon species, though no doubt they, too, will be in the ionic form

Isomerism of Disubstituted Manganese Pentacarbonyl Bromide

THE manganese pentacarbonyl halides react with a variety of ligands of the type PR_3 and $P(OR)_3$ to give mono- and di-substituted products, $Mn(CO)_4LX$ and $Mn(CO)_3L_2X$ [1,2] The reaction of 0 2 g $Mn(CO)_5Br$ with 1 1 g $P(OC_6H_5)_3$ in chloroform at 37° for 12 h yields what is believed to be 1,2-*bis*(triphenylphosphite)-4,5,6-tricarbonyl-3-bromo-manganese(I)[3], in which the $P(OC_6H_5)_3$ groups are *cis* to the Br as well as to each other (the '*cis*-isomer'). However, reaction at 55° produces 1,6-*bis*(triphenylphosphite)-2,4,5-tricarbonyl-3-bromomanganese(I), in which the $P(OC_6H_5)_3$ groups are *cis* to the Br but *trans* to each other (the '*trans*-isomer') Both isomers can be precipitated from chloroform with *n*-hexane and analyse correctly for the above compounds The dipole moments obtained in benzene by an approximate method[4] were 4 8*D* for the *cis*-isomer and 3 5*D* for the *trans*, while $Mn(CO)_5Br$ itself had a moment of 3 4*D* These measurements confirm the assignment of the *trans* structure, but do not distinguish between the possible isomers in which the phosphine ligands are (*a*) both *cis* to the bromide, or (*b*) one *cis* and one *trans* to the bromide An attempt has been made to distinguish these by means of the nuclear magnetic resonance of phosphorus which should show splittings in case (*b*) owing to the different environments of the two ligands Although resonance was observed, the resolution was poor and no conclusion could be reached on these grounds (We thank Dr J Verkade and Dr R King, Iowa State University, for making these measurements) However, in view of the known inertness[5] of the CO *trans* to the bromide in $Mn(CO)_5Br$, we feel that alternative (*b*) is unlikely

The molecular weight of the *trans*-isomer in benzene was 761 (calculated value = 839) The infra-red spectrum of the *cis*-isomer had absorptions in the carbonyl stretching region at 2053(*s*), 2000(*s*), 1949(*s*) cm^{-1}, compared with 2070(*w*), 2000(*vs*), and 1949(*s*) for the *trans*-isomer The infra-red spectrum of the previously reported[1] *cis*-$Mn(CO)_3py_2Br$ was very similar to that of our *cis*-isomer, but that of $Mn(CO)_3[P(C_6H_5)_3]_2Br$, prepared in the manner of Abel and Wilkinson[1], was the same as that of our *trans*-isomer, in disagreement with their assignment of a *cis* configuration It seems, therefore, that the *cis*-isomer is produced at low temperatures as a result of a kinetic effect, whereas the *trans*-isomer is formed at higher temperatures owing to its greater thermodynamic stability The number of absorptions and their intensities are consistent with the C_{2v} and C*s* symmetries characteristic of the *trans*- and *cis*-isomers, respectively

Analogous isomers where $L = P(C_6H_5)Cl_2$, $P(C_4H_9)_3$, and $P(OC_4H_9)_3$ have been prepared and identified by their infra-red spectra The *cis*-$Mn(CO)_3py_2Br$ was found not to isomerize to the *trans* form, nor did the aniline complexes On the other hand, $P(C_6H_5)_3$ formed no disubstituted *cis* product, but at higher temperatures yielded the *trans* compound The ligand, $P(OCH_2)_3CCH_3$ (ref 6), forms the disubstituted *cis* compound which isomerizes at 50° only to the extent of 20 per cent, whereas the above isomerizations go essentially to completion This suggests the importance of steric factors in the isomerization

The kinetics of the *cis* to *trans* isomerizations have been studied in *s*-tetrachloroethane from 50° to 70° The rates are first order in complex and independent of added ligand, L The activation energies increase with changing L in the following order

$$P(C_6H_5)Cl_2 < P(C_4H_9)_3 < P(OC_6H_5)_3 < P(OC_4H_9)_3$$

The $P(C_4H_9)_3$ isomerization was measured in $P(C_4H_9)_3$ solvent due to decomposition in tetrachloroethane , however, solvent effects are very small The *cis*-isomer, $Mn(CO)_3[P(OC_6H_5)_3]_2Br$, in tetrachloroethane at 60° reacts with $P(OC_4H_9)_3$ at about ten times the rate of its isomerization to give *cis*-$Mn(CO)_3$-$[P(OC_4H_9)_3]_2Br$ probably via the mixed *cis*-$Mn(CO)_3$-$[P(OC_6H_5)_3][P(PC_4H_9)_3]Br$ This suggests a dissociative mechanism for the isomerization involving the formation of a five co-ordinated intermediate which reacts with free phosphine to reform the *cis*-isomer with an activation energy roughly 1 kcal/mole less than that for formation of the *trans*-isomer

Hydrogen Bonding and Charge-Transfer Complexes

If equal amounts of trinitrobenzene and a polycyclic aromatic hydrocarbon are dissolved in chloroform and the solution is dried off on to filter paper, a colour often appears due to the formation of a charge-transfer complex The new absorption bears no relation to that of either of the components separately, and may be almost anywhere in the spectrum depending on the hydrocarbon It is generally believed that negative charge is transferred from the hydrocarbon, acting as donor, to the trinitrobenzene, acting as acceptor Other kinds of donor and acceptor are known[1], and a theory of such complexes, base on molecular orbitals, has been given by Mulliken[2]

Interaction under similar conditions but of a different kind was reported by Szent-Gyorgyi between donor-type compounds and acridine[3] In this case a yellow colour was observed, particularly with the carcinogens As he pointed out, there could have been no charge-transfer complex since the colour was always the same, and in any event acridine has negligible acceptor properties in this context There may have been a weak chemical link between the acridine nitrogen and some unsaturated centre in the other molecule, giving the yellow acridinium cation on one side of the associated system A possible bond of this kind should be contrasted with the delocalized electron interaction found in charge-transfer complexes

We have now found that if a weak acid such as acetic acid is applied to the acridine/donor system a new colour appears which is dependent on the nature of the second component Mineral acid, on the other hand, merely intensifies the yellow colour It seems that a charge-transfer complex can be formed between 'acridine acetate' and donor-type compounds, and tests with each of seventy such compounds showed that the depth of colour produced was similar to that which they produced with 2-methyl naphthoquinone This means that 'acridine acetate' has an electron affinity similar to that of the strongest known biological acceptors With mineral acid there is presumably complete ionization of the acridine, and the absence of any charge-transfer colour under these conditions indicates that the interaction is still essentially non-ionic and would take place in the lipid rather than the aqueous phase

One-electron transfer is believed to play an essential part in metabolism, and some water-soluble Krebs-cycle intermediates have recently been shown to have a high affinity for thermal electrons[4] Lipid-soluble acceptors important in metabolism are not so easy to find Some of the ubiquinones were tested for charge-transfer complex formation and found to be rather weak acceptors compared with 2-methyl naphthoquinone The present observations suggest that suitable compounds can become strong electron acceptors by forming a weak reversible chemical link, such as a hydrogen bond, with a carboxylic acid or other compound containing active hydrogen In support of this view, it was found that hexyl resorcinol was able to induce what appeared to be a charge-transfer complex between acridine and the strong donor N,N' tetramethyl-*p*-phenylenediamine Trichloroacetic acid was likewise able to induce a colour change in a mixture of dibenzylidene-acetone and the above-mentioned amine Indolyl-3-acetic acid gave a brown colour with acridine alone, as did indole and acetic acid applied as separate compounds One may speculate that the plant-growth hormone is not only a good electron donor but also carries, in the acetic acid moiety, a means of inducing certain molecules to accept an electron

Szent-Gyorgyi's aqueous FMN-serotonin system[5] also seems to be activated by acid, though it is not known yet whether the mechanisms are related

Chemical Preparation and Electron Spin Resonance Spectra of Specific Trapped Hydrocarbon Radicals

IN recent years there have been many reports of radicals trapped in solid matrices[1] The radicals have been formed by radiolysis, photolysis, or electrical discharge We have now succeeded in developing a general method of preparing specific trapped hydrocarbon radicals by simple chemical reaction, using a rotating cryostat previously described by one of us[2]

The method is to deposit a thin discontinuous film of sodium atoms (far less than a monolayer) on to a freshly prepared moving surface of halogenated hydrocarbon, preferably an iodide, held in a high vacuum at the temperature of liquid nitrogen The atoms react to form the sodium halide and the hydrocarbon radical A fresh layer of the halogenated hydrocarbon is then deposited on top of the products of reaction, which thus become embedded and preserved in a matrix The process is repeated many times to build up an appreciable amount of material A sample of the deposit is then transferred, still cold and under high vacuum, to an electron spin resonance spectrometer, where the electron spin resonance spectrum of the trapped radical is recorded A feature of the experimental method is that only a single free radical reaction step $RX + \text{Na} \longrightarrow R + \text{Na}X$ (X = halogen) is allowed to take place

Table 1 summarizes our results listing the radicals formed, the material of preparation (which was also the matrix in which radicals were embedded), some salient features of the electron spin resonance spectrum and, in some instances, the molar concentration of radicals in the samples transferred to the spectrometer After being warmed to room temperature, some of the samples were analysed by gas liquid chromatography (G L C), with results which are also given in Table 1 The spectra, supported by the analytical results, demonstrate that the radicals formed from the halides were the expected ones

The electron spin resonance spectra of the radicals *n*-propyl, *n*-butyl, *s*-butyl, isobutyl, *t*-butyl, *cyclo*pentyl and *cyclo*hexyl at 77° K are in good agreement with those reported by Ayscough and Thomson[3] while that for allyl is similar to the one reported by Smaller and Matheson[4] In these other investigations the radicals were produced by γ-irradiation of parent molecules, so that the preparation described here, by an entirely different method involving simple chemical reaction, is strong confirmation of the identities claimed The spectra of both phenyl and benzyl radicals exhibit hyperfine structure Detailed discussion of these and the other spectra will be published later

We thank Mr W N Sailes for assistance with the experimental work

New Evidence for Free AlH

RECENT work in this laboratory on the vapour density of the compound, $AlH_3\ 2N(CH_3)_3$, has indicated that this material dissociates reversibly in two steps In Table 1, the pressures at various temperatures are presented for a sample of known weight in a volume of approximately 1 litre The pressures, measured with a mercury manometer, have been corrected to 0°

Table 1 DISSOCIATION PRESSURES OF $AlH_3\ 2N(CH_3)_3$

			389 36	0 9781	25 36
			391 22	0 9781	25 44
			398 19	0 9781	26 18
			402 79	0 9781	26 40

The molecular weights calculated from the ideal gas law and the data in Table 1 are plotted in Fig 1 The data for the large (0 1477 gm) sample (curve *a*)

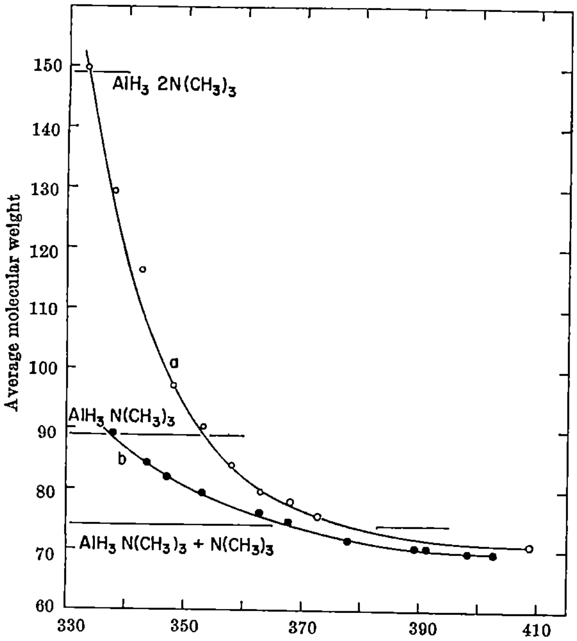

Fig. 1. Molecular weight of $AlH_3\ 2N(CH_3)_3$

obviously indicate the presence of a condensed phase of variable composition and it is not obvious at what point complete vaporization has occurred. However, it is evident that the curve represents an upper limit for the average molecular weight of the system. Curve (*b*) represents the data relative to the smaller (0.07173 gm.) sample and suggests complete vaporization at a lower temperature. For both samples, every other data point was recorded in order of ascending temperature, the remaining points, in order of descending temperature. On cooling to room temperature, the pressure in the system was reduced to 1.80 mm., the original value at the start of the experiment. The pressure was reduced to zero at −196° C. Thus the dissociation at higher temperatures appears to be reversible with no irreversible pyrolysis of the AlH_3 moiety.

Assuming that the second dissociation step is negligible at lower temperatures, equilibrium constants can be evaluated from the data of set (*b*) below 360° abs. for the reaction $AlH_3\ 2N(CH_3)_3 = AlH_3\ N(CH_3)_3 + N(CH_3)_3$. These can be represented by the following equation:

$$\log_{10} K_{p1\,(\text{mm.})} = 11.971 - 3937.0/T$$
$$\Delta H_1 = -18.0 \pm 0.1 \text{ kcal/mole}$$

These values are felt to be quite reasonable, since ΔH_1 indicates that $AlH_3\ N(CH_3)_3$ is Lewis acid of strength comparable with $B(CH_3)_3$ towards $N(CH_3)_3$. The enthalpy increment in the case of $B(CH_3)_3$ is −17.6 kcal/mole[1].

It can be seen that, at room temperature, the pressure of $AlH_3\ N(CH_3)_3$ in equilibrium with a similar pressure of $N(CH_3)_3$ and solid $AlH_3\ 2N(CH_3)_3$ will amount to nearly 0.3 mm. This will account for the fact that crystals of the compound seem to emit smoke even in a relatively dry atmosphere while the crystals themselves remain undecomposed. Evaporation from the surface of the crystals is followed by dissociation and, in the presence of very slight traces of moisture, the $AlH_3\ N(CH_3)_3$ would be expected to co-ordinate a water molecule:

$$H_2O + AlH_3\ N(CH_3)_3 = H_2O\ AlH_3\ N(CH_3)_3$$

The resulting complex, containing both acidic and hydridic hydrogen, would decompose rapidly, perhaps through several steps and further addition of water, to yield Al_2O_3, H_2 and $N(CH_3)_3$.

It is apparent from Table 1 and Fig. 1 that the concentration of any dimeric species such as the structure proposed by Wartik[2] for $AlH_3\ 2N(CH_3)_3$ must be very low indeed. Further evidence from crystallographic studies and gas phase absorption spectra for a monomeric structure will be presented later.

It is also apparent from the data presented here that a second reversible reaction occurs at higher temperatures, to give products lighter than $AlH_3 \cdot N(CH_3)_3$. Such a reaction might be

$$2AlH_3\ N(CH_3)_3 = [HAl\ N(CH_3)_3]_2 + 2H_2$$

However, it is doubtful that such a reaction would be reversible and it is felt that a simple dissociation into AlH_3 and $N(CH_3)_3$ is more likely. The state of polymerization of AlH_3 is not evident from the present data, nor is the possibility of a species such as $(AlH_3)_x\ N(CH_3)_3$ eliminated. Attempts to evaluate equilibrium constants for the second step in the dissociation $AlH_3\ 2N(CH_3)_3$ were inconclusive. Work is at present in progress to obtain more accurate data on this system.

This work was performed in the Ames Laboratory of the U.S. Atomic Energy Commission.

Zwitterion Ratios of *N*-(Substituted Phenyl)-Glycines: the Non-Validity of the Ebert–Wegscheider Assumption

DURING the course of our investigation of acid-base equilibria in *N*-(substituted phenyl)glycines it has become apparent that the well-known Ebert–Wegscheider[1] assumption equating the inductive effect of a carboxy group with that of a carboethoxy or carbomethoxy group is invalid when applied to these acids. This assumption has been widely used to evaluate the microscopic or individual constants for the following reactions[2]:

$$R\overset{+}{N}H_2\,CH_2\,COOH \overset{K_A}{\rightleftarrows} R\overset{+}{N}H_2\,CH_2\,COO^- + H^+ \quad (1)$$

$$R\overset{+}{N}H_2\,CH_2\,COOH \overset{K_B}{\rightleftarrows} R\,NH\,CH_2\,COOH + H^+ \quad (2)$$

$$R\overset{+}{N}H_2\,CH_2\,COO^- \overset{K_C}{\rightleftarrows} R\,NH\,CH_2\,COO^- + H^+ \quad (3)$$

$$R\,NH\,CH_2COOH \overset{K_D}{\rightleftarrows} R\,NH\,CH_2\,COO^- + H^+ \quad (4)$$

from the experimentally measured ionization exponents pK_1 and pK_2, K_B being assumed equal to the ionization constant, K_E, for the reaction

$$R\overset{+}{N}H_2\,CH_2\,COOEt \rightleftarrows R\,NH\,CH_2\,COOEt + H^+ \quad (5)$$

The zwitterion constant K_Z for the equilibrium

$$R\,NH\,CH_2\,COOH \rightleftarrows R\overset{+}{N}H_2\,CH_2COO^-$$

is readily calculated from the relation $K_Z = \dfrac{K_A}{K_B} = \dfrac{K_D}{K_C}$.

Table 1 SOLVENT WATER TEMPERATURE, 25.0°

Substituent	K_A	pK_1	pK_B	pK_E	pK_B-pK_E
m-nitro	very small	0.06 ± 0.05	0.06	−0.17 ± 0.05	0.23

					Mean 0.20 ± 0.03_5

When an attempt was made to apply this method to the evaluation of the constants for the *N*-(substituted phenyl)glycines, anomalies soon became apparent. Thus in the predominately non-zwitterionic *N*-(*m*-nitrophenyl)glycine, the first dissociation constant K_1 was found to be smaller than that of the ester K_E whereas the lower limit for K_1 is equal to K_E if the Ebert–Wegscheider assumption is correct, this occurring when $K_A = 0$. An alternative method for the determination of the zwitterion equilibrium constants based on spectrophotometric measurements was therefore used from which independent estimates of pK_B were obtained. The cationic, molecular and anionic spectra of the acids, R Ph NH CH_2 COOH, have been compared with those of the molecular and cationic species of the correspondingly substituted ethyl esters, the substituent R being varied through the series *m*-NO_2, *m*-CN, *m*-Cl, *m*-$COCH_3$, *p*-Cl, *m*-OMe, H, *m*-Me, *p*-Me, *p*-OMe. We find that for the non-zwitterionic *m*-nitro-phenylglycine the spectra of the anionic and molecular species of the acids are virtually identical with those of the molecular species of the ester. However, as the substituent changes in the order stated, there is an increasing divergence from this state through the above series and this is coupled with an increasing similarity between the molecular form of the acid and the cations of both acid and ester. Thus in other cases in which an equilibrium is present, the relative concentrations of zwitterion and non-zwitterion may be determined spectrophotometrically, the optical density at any wave-length being intermediate between that of the cation, which gives the optical density which would be observed if the equilibrium were virtually all zwitterion, and that of the molecular form of the ester, the absorption of which corresponds to that of the non-zwitterionic molecular form of the amino-acid.

These results are shown in Table 1.

The values in the last column show a mean of 0.20 ± 0.03_5 and appear to bear no relation to the σ_m values of the substituents. Thus the inductive effect of a —COOEt group in these compounds is greater than that of a —COOH group by 0.20 units. It is impossible to extend this conclusion to α-amino aliphatic acids since these are almost entirely zwitterionic and no estimate of pK_B can be drawn from the experimental data. There are, however, numerous systems in which zwitterion estimates have been based on the Ebert–Wegscheider assumption and these may require to be checked by an independent criterion. Details of this work including discussions os the Hammett constants for reactions, 1, 2, 3, 4 and 5 (where R = X Ph) will be published elsewhere.

BIOPHYSICS

Reversible Reaction of Double-Stranded Polynucleotides and Hg^{II}: Separation of the Strands

THE reaction of double-stranded deoxyribonucleic acids (DNA) and mercuric compounds[1] proceeds by two principal steps[2–4]. In the DNA's occurring naturally, these steps can be demonstrated and defined by the presence of isobestic points in the ultraviolet spectra of the equilibrium mixture. The first reaction occurs in the region $0 \leqslant r \leqslant 0.5 - 0.6$, the second, in the region $r \geqslant 0.5 - 0.6$, where, as usual, the quantity r is defined as the number of moles of Hg^{II} added per mole of nucleotide.

I have recently shown[5,6] that in the range $0 \leqslant r \leqslant 0.5$ the reaction can be largely understood as the formation of 2 : 1 base-Hg^{II} complexes which form base–*N*–Hg^{II}–*N*–base 'bridges' between the two strands of the DNA double helix.

The preference, at *p*H 5.6, for the 2 : 1 bridge complexes of thymidine deduced earlier[5,6] has since received indirect confirmation especially applicable to the reaction of Hg^{II} and the highly ordered, synthetic polydeoxyribonucleotide, poly (A—T). Ferreira *et al.*[7] have shown that for the isolated nucleosides one can write

$$Hg^{++} + 2T \rightleftharpoons HgT_2 + 2H^+ \qquad K = 10^{2.0} \qquad (1)$$

$$Hg^{++} + 2A \rightleftharpoons HgA_2^{++} \qquad K = 10^{8.5} \qquad (2)$$

where T and A represent neutral thymidine and neutral adenosine.

According to the theory of the reaction[5,6] and the theory of site binding in polyfunctional reactants[8] the equilibrium constants in (1) and (2) are directly applicable to the case of DNA, so the preference of Hg^{II} for thymidine, at *p*H 5.6, may be considered confirmed.

There is therefore an accumulation of evidence to support the view[5,6] that at $r = 0.5$ the reaction product of DNA and Hg^{II} may be described chemically as a two-stranded polynucleotide in which nearly all the bases on a given strand are connected to a base on the opposite strand by a Hg^{II} bridge.

What, then, is the nature of the reaction for $r > 0.5$? In view of the mechanism, briefly described here and discussed in greater detail elsewhere[5,6], to ask the question is virtually to answer it: the chemical mechanism for $r \leqslant 0.5$ strongly suggests that the principal reaction occurring when $r > 0.5$ is

$$\text{chain–base–Hg}^{II}\text{–base–chain} + \text{Hg}^{II} \rightleftharpoons \text{chain–base–Hg}^{II} \quad \text{Hg}^{II}\text{–base–chain} \qquad (3)$$

In equation (3), 'chain' represents one of the two strands of DNA helix. Reaction (3) represents the separation of the strands at a given point by the formation of the 1 : 1 base–Hg^{II} complexes.

This kind of strand separation is readily distinguishable from that produced by thermal means in that the totality of evidence very strongly suggests that no irreversible chemical damage of any sort—release of purines, degradation of the phosphate ester backbone or whatever—has occurred[1–4,9,10]. It differs also in specificity: clearly, by manipulating the *p*H and the Hg^{II} concentration one can select the reactive sites reasonably quantitatively within limits imposed by the various equilibria involved.

The best evidence for strand separation of the type described is the chemical mechanism of the reaction[5,6] Additional evidence of a more fragmentary nature but nonetheless consistent with the basic idea is that mercurated DNA at $r = 1\ 0$ shows[4] a small decrease in 'melting point' relative to mercurated DNA at $r = 0\ 5$ The simplest interpretation of this fact is that some of the Hg^{II} bridges have become disrupted by reaction (3)

Applied to poly(A–T), the mechanism outlined above readily allows calculation of the minimum number of broken bridges at $r = 1\ 3$ (the upper limit of the available experimental data[4]) In the Hg^{II} excess region, the reactions would be those in the polynucleotide analogous to

$$HgT_2 + Hg^{++} \rightleftharpoons 2HgT^+ \qquad K = 3\ 6 \qquad (4)$$

$$HgA_2^{++} + Hg^{++} \rightleftharpoons 2HgA^+ + 2H^+ \quad K = 4 \times 10^{-5}\ ^{5}\ (5)$$

in the isolated nucleosides (The equilibrium constants in equations (4) and (5) were derived from data in ref 7)

Noting that only reaction (5) releases hydrogen ion and assuming only reactions (4) and (5) for $r > 0\ 5$, it is easy to calculate that 32 per cent of all the A–Hg–A bridges are broken at $r = 1\ 3$ The calculation was made not on the basis of the equilibrium constants given above but on the average hydrogen ion release[4] by mercurated poly(A–T) for $0\ 5 \leqslant r \leqslant 1\ 3$ The value 32 per cent represents, minimally, 16 per cent of all the Hg^{II} bridges in poly(A–T) since the polymer contains equal moles of A and T and, according to (4), a small fraction of the T–Hg–T bridges will also be disrupted Obviously, these will not be apparent in pH-stat studies[4]

It is (now) equally obvious, but no doubt worth emphasizing, that in addition to its suitability as a reagent in the study of other aspects of polynucleotides[5,6], Hg^{II} may also serve as a reagent of intrinsically desirable and unique characteristics for the separation of the strands of double-stranded polynucleotides Studies of this aspect of the reaction will be reported in due course

Deoxyribonucleic Acid Code

IN the past few months very important advances have been made concerning how the sequence of nucleotides in DNA corresponds to amino-acid sequences in protein synthesis The work of Crick *et al* [1] of Matthaei and Niremberg[2–4] and of Ochoa *et al* [5–7] gave definite answers to particular questions concerning the code in which information is written in DNA or RNA It seems that such findings are even too abundant and precise, and at first sight it seems to be not an easy task to put all results together

Table 1

19	*GGT*	*TGG*	*CCA*	*ACC*
20	*GTG*		*CAC*	

For that reason it appears worth while to consider once more the code problem from the abstract point of view, starting from a very small number of reasonable postulates, suggested partly by experiments, without expecting the final solution from experiments themselves

A conclusion of Crick's work is that a triplet of nucleotides incorporates a particular amino-acid in proteins All triplets are significant so that the code is degenerate (and it is also comma-less)

We can take this as a starting point (postulate No 1) In that case it seems to me almost necessary to admit that complementary triplets such as *TAC* and *ATG* correspond to the same amino-acid (postulate No. 2) We avoid in this way the difficulty of establishing which of the two strands of DNA must be read

Furthermore, it seems very reasonable to admit that each strand can be read upward and downward without changing the sense of the message (postulate No 3) So the two triplets *TAC* and *CAT* should not be considered different triplets

With these three postulates, the 64 triplets are grouped in exactly 20 groups as is shown in Table 1 Each group must correspond to a different amino-acid and the triplets of the same group must correspond to the same amino-acid

Referring to the code in Table 1, it is not necessary to admit that all the triplets of the same group do work exactly in the same way in incorporating amino-acid The most probable thing we can suppose is that the reaction-rates are different from triplet to triplet in the same group, so that we can find just one triplet in each group to which corresponds the maximum reaction-rate at first sight the code will then appear as non-degenerate and only one strand of the DNA will work in practice Furthermore, we can suppose that every cystron must have the most reacting triplets all on one strand, but different cystrons must not have them always on the same strand So for certain cystrons one strand of the DNA will work and for other cystrons the other

Secondly, if we examine Table 1 from the point of view of combination, we see that each particular base is present in seventeen groups out of twenty

This result is in striking agreement with Ochoa's work if we suppose that the triplets that contain a particular base say uracil in RNA, do have a particularly high reaction-rate

In general, we can suppose that triplets with two or more purines (column *a*, Table 1) differ in stability and reactivity from complementary triplets with two or more pyrimidines (column *b*, Table 1) In that case, when we certainly have all the cystrons on the same strand as in Ø*X*174, the complementary strand must have different mean base composition, as it is observed[8] The same situation holds for some RNA viruses[9], as is well-known, and perhaps also for the α-phage of *B megatherium*, on which Graziosi *et al* are working[10]

Furthermore, if we make fragments of DNA sufficiently short so that each fragment is of the order of one cystron only, we must observe similar irregularities in base composition of the two strands

Several experiments can be devised to test the code of Table 1, but these are not discussed here On the contrary, it is necessary to say that some of Ochoa's results cannot be foreseen by this code If confirmed, they would disprove postulate No 2 and then the code must necessarily be rejected Nevertheless, it seems to me very difficult to admit that complementary triplets may have different meanings, and to reconcile the experimental percentage of *U* in RNA with Ochoa's triplets, other than with a mechanism of degeneracy of the type considered here. Obviously, a more detailed discussion of all the experimental results is necessary

Note After this communication was written I found that the same code was considered by the Russian physicist V V Chavchanidze[11] I would direct attention to his paper, for it appears even more suggestive in view of the new experimental results

Experimental Evidence for the Degeneracy of the Nucleotide Triplet Code

EXTENSIVE investigations have been reported recently of the incorporation of labelled amino-acids in cell-free protein-synthesizing systems to which synthetic polynucleotides of known compositions were added The results have led to the assignment of coding triplets to each of the 20 naturally occurring amino-acids[1,2] The peculiar feature of these codes is the presence of at least one uracil residue in each of the 20 triplets

Although the composition of RNA isolated from various sources bears no relationship to the composition predicted by this code[3], many attempts have been made to explain naturally occurring or nitrous acid induced mutations, that is, amino-acid replacements[4,5], on the basis of a single nucleotide change in one triplet of the coding RNA In view of this, we would like to offer experimental evidence of the impossibility of an *in vivo* coding system of the composition as proposed so far In the following argument only one assumption has been made, namely. that the RNA of the plant viruses codes for viral protein

We investigated the structure and composition of the satellite component of tobacco necrosis virus, the smallest virus so far discovered[6] From sedimentation-diffusion measurements we found its molecular weight to be 1 97 × 10^6 The RNA content of the virus we found to be 20 per cent by weight, which indicates a maximum molecular weight for the RNA of 394,000 The sedimentation coefficient of the isolated RNA was 13 5*S*, suggesting that it occurs as a single molecular species From its base composition (U = 24 9 per cent, C = 22 1 per cent, A = 28 0 per cent, G = 25 0 per cent) and molecular weight, the RNA chain would consist of 1,160 nucleotides or 387 triplets From the amino-acid composition of the viral protein, the minimum molecular weight of the protein was about 25,000, corresponding to 240 amino-acid residues The coding of this protein would therefore require about 720 nucleotides, or 60 per cent of the total RNA chain From the coding triplets published in the literature and the amino-acid composition of the viral protein it can be readily calculated that all the uracil residues of the viral RNA must be in the coding part while the remaining 40 per cent of the RNA chain would contain no such residues Moreover, the maximum number of nucleotide residues between two uracils cannot exceed four in the coding part of the RNA

To check the nucleotide distribution along the RNA chain, the isolated RNA was digested with pancreatic ribonuclease, a highly specific enzyme which only splits the 3′-phosphodiester bonds of pyrimidine nucleotides The nucleotides in the digest were separated on a diethylaminoethyl cellulose column, and the amounts of the various oligonucleotide fractions determined[7] The last fraction eluted from the column contained 13 2 per cent (molar) of the total digest and had an average chain-length of 6 3 nucleotides The C U ratio in this fraction was 0 92 and was closely similar to that found in the whole digest (0 89) From the above considerations one would expect this fraction to contain no uracil at all

The considerations in the last paragraph apply to the code derived from studies on synthetic polynucleotides regardless of sequence within the individual triplets If a comparison between the suggested sequences[4,5] and our data is made, the discrepancy is even more pronounced Taking the 240 base triplets from any one of the six sequences arrived at by E L Smith[4], the maximum amount of uracil in the fractions containing tetra- and higher nucleotides could not exceed 0 36 per cent (molar) However, it was found that these fractions amounted to 28 per cent of the total digest and contained 11 per cent of the total uracil content of the viral RNA

In view of these results one must conclude that either the sets of nucleotides coding individual amino-acids are not unique (degeneracy), or that the code is not a universal one

Another consequence of this work is that the ratio of nucleotides to amino-acids (coding ratio) must be less than 5 in this virus Together with the evidence of Crick *et al* [8], this strongly suggests that the coding ratio is 3

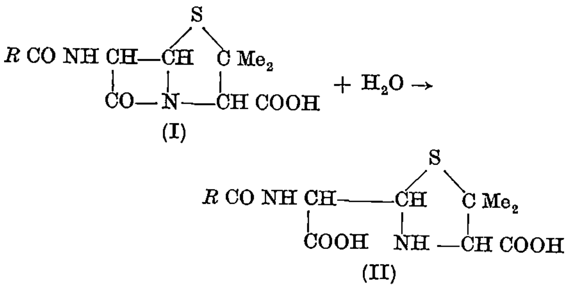
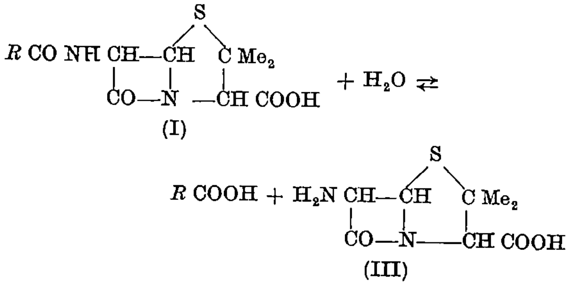
BIOCHEMISTRY

Formation of 6-Aminopenicillanic Acid by Alkaline Hydrolysis of Penicillins

Two groups of enzymes hydrolyse penicillins (I) The earlier of the two to be reported was penicillinase[1], which opens the β-lactam ring to form the corresponding penicilloic acid (II)



More recently a number of workers have reported the enzymatic removal of the side-chain[2-5] to give 6-aminopenicillanic acid (6-APA) (III)



Alkaline hydrolysis of penicillins gives virtually quantitative conversion to the corresponding penicilloic acid This quantitative conversion is the basis of some chemical methods of estimating penicillin The iodometric method depends on the iodine uptake of the penicilloic acid formed It was interesting to find that with certain penicillins alkaline hydrolysis can also remove the side-chain and under certain conditions as much as 1 per cent of the penicillin can be converted to 6-APA

When phenoxymethylpenicillin was stored between *p*H 2 and *p*H 7 no 6-APA formation could be detected, but above *p*H 7 the amount of 6-APA increased with the *p*H, until above *p*H 11, when both 6-APA and phenoxymethylpenicillin were rapidly destroyed The amount of 6-APA formed increased considerably at higher temperatures, and when the penicillin was stored at *p*H 8 5 the Q_{10} was about 2 over the range 25°–70° C

Table 1 EFFECT OF TEMPERATURE
5 mg/ml phenoxymethylpenicillin stored in 0 05 M phosphate *p*H 8 5 for 3 h

Temperature (° C)	μg/ml 6-APA formed	Temperature (° C)	μg/ml 6-APA formed
25	0 5	55	7 5
37	2 0	70	16 0
45	4 5		

The presence of phosphate seemed to have a definite effect on the amount of 6-APA formed, the yield in the presence of phosphate buffer being several times higher than when a borate buffer was used or when the *p*H was kept constant by the automatic addition of sodium hydroxide

The possibility of contamination by micro-organisms was unlikely in view of the high *p*H and temperature at which the phenoxymethylpenicillin was incubated, and when aseptic precautions were taken the yield of 6-APA was completely unaffected Similarly, the possibility of any amidase enzyme being present on the glassware was eliminated by the use of new and specially cleaned equipment

A number of penicillins were found to give rise to small amounts of 6-APA under alkaline conditions but phenoxymethylpenicillin was the most labile

Table 2 RELATIVE 6-APA FORMATION FROM DIFFERENT PENICILLINS
1 per cent solution of penicillin in 0 05 M phosphate *p*H 8 5 for 5 h at 70° C

Penicillin	μg/ml / 6-APA formed
Phenoxymethyl	30
Phenoxybenzyl	17
Phenoxyethyl	2 6
2 6-Dimethoxyphenyl	2 0
Phenoxypropyl	<2 0
Benzyl	<2 0

It is possible that detailed examination of the alkaline hydrolysate would reveal that a greater percentage of the side-chain was removed because, though somewhat more stable than phenoxymethylpenicillin, 6-APA is itself readily hydrolysed

Variations in the α_s-Casein Fraction of Individual Cow's Milk

We have investigated variations in the α_s-casein fraction[1], the calcium-sensitive component of α-casein and a major protein fraction of the casein family. Recently, Aschaffenburg[2] demonstrated the heterogeneity of β-casein and also noted the presence of γ-casein variants. The existence of 5 out of 6 possible phenotypes for β-casein was shown by paper electrophoresis in a citrate–phosphate–urea buffer at *p*H 7·15. The evidence presented suggested that β-casein polymorphism may be restricted to Channel Island breeds. Heterogeneity of α_s-casein fraction was not noted.

The components of the α-casein complex are not conveniently observed by conventional electrophoretic methods. However, the use of starch-gel-urea electrophoresis at *p*H 8·6 has proved to be an extraordinarily good method for separation of casein components. Using this technique, we investigated the homogeneity of the α_s-casein fraction. For determination of molecular parameters and structural features of this protein, assurance of its homogeneity is imperative. In addition, the detection of heterogeneity in α_s-casein would be important since the heterogeneity could possibly be related to the physical instability of the calcium caseinate complex in milk.

Individual bovine milks (Holstein, Brown Swiss × Holstein, and Ayrshire × Holstein) were selected for examination. They were obtained from the U.S. Department of Agriculture herd at Beltsville, Maryland. To prepare the samples, gravity-separated milk was precipitated at *p*H 4·6 and 22°–24° C. The precipitate was washed four times with water and ethanol, twice with acetone and twice with ethyl ether. Starch-gel-urea electrophoresis, as described by Wake and Baldwin[3], was run on casein solutions containing 7 mg casein per millilitre of buffer-urea solution. Approximately 5 V cm^{-1} was applied to the gel for 17 h, after which it was developed with amido black dye.

On examination of caseins from 93 individual cows by starch-gel-urea electrophoresis, patterns identical to pooled-milk caseins were usually obtained. However, in six cases an additional band appeared in the region ascribed to calcium-sensitive α-casein (α_s). The six individuals were all daughters of one sire, an observation which suggested a genetic basis for the heterogeneity.

Fig. 1 shows starch-gel-urea electrophoresis patterns of individual caseins, the larger numbers (3451, 3865, etc.) referring to the animal number. Patterns 1 and 7 are like patterns obtained with pooled whole casein whereas the remainder of the patterns show a double α_s band referred to as α_s-A and α_s-B in order of decreasing mobility. The use of A and B further denotes genetic nomenclature of the α_s-caseins. All other caseins studied show α_s-B casein, but α_s-A has not been observed alone to date. On mixing equal quantities of α_s-B and α_s-A/B caseins and examining the pattern on starch-gel-urea electrophoresis, a pattern typical of α_s-A/B is obtained except that α_s-A is diminished in concentration. Little question exists that α_s-B from α_s-A/B and homozygous α_s-B are identical, but isolation and characterization will be the only unequivocal proof.

In regard to the occurrence of the α_s-A/B split over the course of lactation, we have observed with cow number 4001 that the heterogeneity occurred throughout a complete single lactation and into the next. Other animals (both α_s-A/B and α_s-B) have been examined within the same lactation with identical results.

The α_s-A/B heterogeneity is detectable in veronal buffer at *p*H 8·6, $\Gamma/2 = 0{\cdot}10$, in free boundary electrophoresis, and a bimodal schlieren pattern was observable in the ultracentrifuge at *p*H 7·0, $\Gamma/2 = 0{\cdot}20$ in phosphate buffer. Urea fractionation[4] yields both α_s-A/B in the 4·7 M insoluble fraction. Subsequent treatment of α_s-A/B with calcium chloride reveals that both are calcium-sensitive. In addition, α_s-A/B caseins are eluted together from DEAE-cellulose-urea chromatographic columns[5].

As already mentioned, the double α_s band has been observed only in caseins from daughters of a single sire (*P*-17). Of 14 daughters of this sire in the Beltsville herd, six showed the heterogeneity. These daughters are coded as 3865, 3866, 3869, 3870, 3889 and 4001 (all Holstein). At this point of the investigation little can be said of the genetic nature of the occurrence of α_s-A/B casein. However, the examination at this time is centring around studying daughter–dam pairs of the *P*-17 sire. In addition, we are seeking the possible occurrence of cows producing only α_s-A casein.

Note added in proof. Since the preparation of this manuscript an additional variant (α_s-C) has been

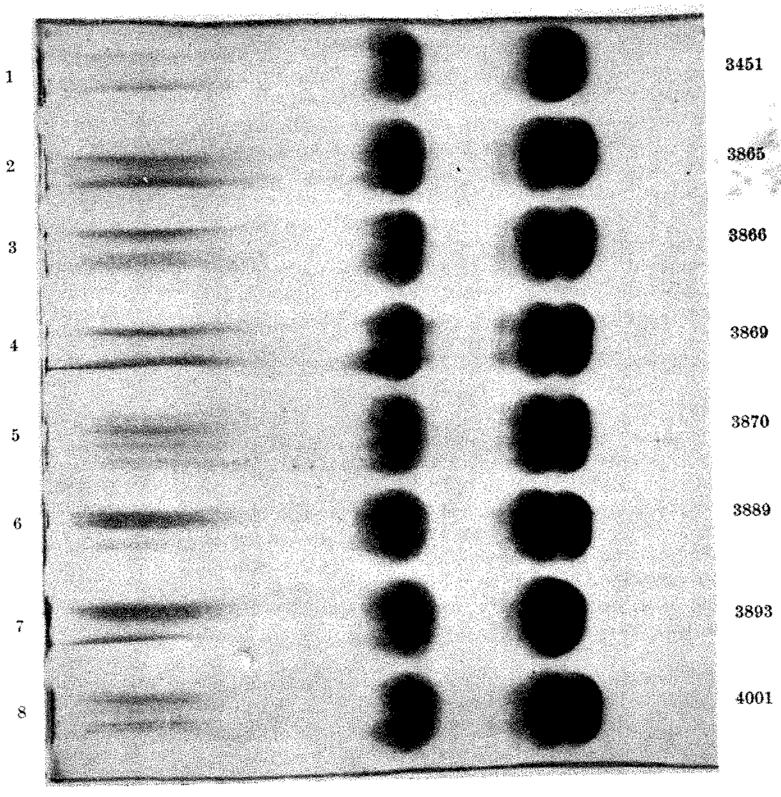

Fig. 1. Starch-gel-urea electrophoresis patterns of casein from individual cows

discovered with the co-operation of Dr. R. Aschaffenburg, Reading, England. This discovery does not alter the acceptable nomenclature of α_s-*A* and α_s-*B*, and a detailed report of its occurrence is in preparation.

Poly-α-amino-acids containing L-Glutamyl Residues as Substrates for Pepsin

In a study of the action of pepsin on various poly-α-amino-acids we have found that poly-L-glutamic acid as well as some amino-acid copolymers containing L-glutamic acid residues are readily hydrolysed by pepsin. Digestion was tested at 35° in 3 ml. solutions containing 12 mg of polyamino-acid[1] and 0·8 mg crystalline pepsin, adjusted to *p*H 2·3. Since most of the polypeptides investigated do not dissolve directly at acid *p*H, they were dissolved in the minimal amount of 0·1 N sodium hydroxide, and the required *p*H was obtained by adding 0·1 N hydrochloric acid. Hydrolysis was followed by measuring : (*a*) the uptake of acid in the *p*H-stat ; (*b*) the increase in the colour produced with ninhydrin[2] ; (*c*) the increase in Van-Slyke amino-nitrogen. Fair agreement was found in the results obtained by the foregoing three methods. The peptic digests were analysed by descending paper chromatography in *n*-propanol/water/concentrated aqueous ammonia (100 : 50 : 1 v/v). The chromatograms were run for 48 h, and were revealed with ninhydrin.

The following poly-α-amino-acids were resistant to peptic action : poly-L-aspartic acid, poly-L-lysine, poly-DL-alanine, poly-L-serine, poly-L-proline, poly-hydroxy-L-proline and the water insoluble poly-L-phenylalanine and poly-L-tyrosine.

Approximately 16 per cent of the peptide links of a poly-L-glutamic acid preparation, with an average degree of polymerization $n = 125$, were hydrolysed within 30 min. No marked increase in the extent of hydrolysis occurred on additional incubation for 24 h. From the uptake of hydrochloric acid at *p*H 2·3 an initial rate of hydrolysis of 3·0 μmoles peptide bond per min per mg of pepsin was calculated, assuming a negligible extent of ionization of the newly formed carboxyl groups. The rate of hydrolysis of poly-L-glutamic acid is thus very markedly greater than that of low molecular weight synthetic pepsin substrates[3].

Oligopeptides containing 2–9 glutamic acid residues could readily be detected on paper chromatograms of the peptic digests of poly-L-glutamic acid. High oligopeptides Glu$_4$ to Glu$_9$ appear in the incubation mixture at the initial stages of the enzymatic reaction (10–30 min of incubation). Further incubation results in their conversion into lower oligopeptides, triglutamic acid being the major product of exhaustive enzymatic hydrolysis. Synthetic α,L-glutamyl oligopeptides (Glu$_2$ to Glu$_8$)[4] were used as markers in these experiments.

Chromatographic analysis revealed that under the experimental conditions used, synthetic α- di-, tri-, and tetra-L-glutamic acids are essentially resistant to hydrolysis by pepsin. Penta-, hexa-, hepta- and octa-L-glutamic acids, however, are readily hydrolysed, mainly to triglutamic acid.

The rate of enzymatic hydrolysis of poly-L-glutamic ($n = 125$) at 35° decreased approximately 100-fold, on increasing the *p*H from a value of 2·3 to 4·5. The relatively low rate of peptic digestion of poly-L-glutamic acid at *p*H 4–4·5 is in accord with the recent findings of Simons *et al.*[5].

Copolymers of L-glutamic acid with D-glutamic acid, L-aspartic acid, L-lysine, L-alanine, L-tyrosine or L-phenylalanine were also tested for susceptibility to peptic digestion. Copolymers with relatively high L-glutamic acid content, such as L-Glu : D-Glu (molar residue ratio 11 : 1), L-Glu : L-Asp (9 : 1) or (5 : 1) and L-Glu : L-Tyr (9 : 1) were hydrolysed at a rate and to an extent similar to those of poly-L-glutamic acid. Copolymers with relatively low contents of L-glutamic acid were hydrolysed at slower rates and to lesser extents than poly-L-glutamic acid. The copolymers L-Glu : D-Glu (1 : 1), L-Glu : L-Asp (1 : 5) and L-Glu : L-Lys (1 : 5) were resistant to peptic digestion.

Since the high-molecular-weight poly-L-glutamic acid is readily hydrolysed by pepsin at *p*H values (*p*H 2·3–4·0) at which the substrate molecules possess a helical conformation[6], it seems that pepsin might act on polypeptides possessing a specific macromolecular stereochemical structure. A similar conclusion was reached recently by Simons *et al.*[5] from their investigation of the action of pepsin on poly-L-glutamic acid at *p*H 4·18.

The formation of the high oligopeptides at the initial stages of the enzymatic hydrolysis of poly-L-glutamic acid suggests that pepsin acts on the high-molecular-weight synthetic substrates by an 'intermediate' mechanism[7]. Our experimental findings rule out for pepsin a 'one by one' mechanism[7], in accord with the findings of Ginsburg and Schachman[8].

We thank Mr. I. Jacobson for the preparation of the polyamino-acids and Dr. Y. Levin for the synthesis of the glutamic acid oligopeptides.

This investigation was supported in part by grant No. *A*-3083 of the National Institutes of Health, U.S. Public Health Service.

Comparison of Bovine and Human Orosomucoids

THE existence of acidic glycoproteins in human[1-3] and bovine[4,5] sera has been well established A bovine M-2 glycoprotein has been isolated in an apparently pure state as described by us earlier[5], and bovine orosomucoid has been purified by Weimer and Winzler[4] This communication describes the isolation of reasonably homogeneous bovine orosomucoid and discusses its properties in relation to the corresponding human material

Human orosomucoid was prepared from fraction VI as previously described[3] Bovine orosomucoid was prepared from a bovine plasma fraction by the carboxymethyl cellulose method[5] Orosomucoid was the only protein not retained by the carboxymethyl cellulose exchanger, equilibrated with pH 4 1 acetate buffer, ionic strength 0 033, when plasma ammonium sulphate fraction P-4 (ref 4) was applied to it at pH 4 1 (acetate) Apparent purity of the bovine orosomucoid preparation was determined by filter paper- and cellulose acetate paper-electrophoresis at pH 4 5, 7 0 and 8 6 In all cases the orosomucoid preparation showed only one band when paper strips were stained for protein (bromphenol blue and Ponceau S) and for carbohydrate (periodate-permanganate[6]) The preparation also appeared homogeneous in the ultracentrifuge at concentrations 3 2 mg/ml –10 mg/ml giving a $S_{w,20}$ of 3 2 at infinite dilution Intrinsic viscosity, determined by plotting relative viscosities versus concentration, was 0 076 Partial specific volume was 0 714, calculated from composition data Molecular weight of bovine orosomucoid, calculated from the above data, was 49,000 Amino-acid composition, except tryptophan, was determined by the method of Moore *et al* [7], tryptophan was determined according to Bencze and Schmid[12], and carbohydrates were estimated as described by Winzler[8] and Dische[9] Sialic acid was determined by the Ehrlich reaction[10] and by the orcinol method[11] Table 1 summarizes properties of bovine and human orosomucoids

Only minor differences in the amino-acid, hexose, and hexosamine content of the two proteins are apparent The sialic acid content in bovine orosomucoid was somewhat higher than in the human preparation, although by paper- and moving boundary-electrophoresis methods bovine orosomucoid has a mobility towards the anode of only 75 per cent that of human orosomucoid at pH 4 5 The sialic acid content of bovine orosomucoid, prepared in our laboratories, was also considerably higher than that of purified bovine orosomucoid as reported by Weimer and Winzler[4] Minor differences in amino-acid composition also exist between human orosomucoid reported herein and orosomucoid isolated by Weimer *et al* [1] In the latter case, amino-acids were determined microbiologically

Table 1 COMPOSITION AND PROPERTIFS OF BOVINE AND HUMAN OROSOMUCOIDS

	Bovine (per cent)	Human (per cent)
Nitrogen	11 1	11 1
Lysine	6 10	4 72
Histidine	1 57	1 13
Ammonia	1 51	1 95
Arginine	3 39	3 33
Aspartic acid	5 84	6 08
Threonine	3 37	4 02
Serine	2 87	1 62
Glutamic acid	10 50	10 10
Proline	1 57	2 06
Glycine	1 44	1 22
Alanine	3 11	1 87
½ cystine	1 64	1 08
Valine	2 22	2 55
Methionine	0 74	0 50
Isoleucine	3 30	2 65
Leucine	3 91	4 27
Tyrosine	3 36	4 52
Phenylalanine	8 85	7 12
Tryptophan	0 75	1 70
Hexose	12 0	14 4[3]
Hexosamine	11 8	10 2[3]
Sialic acid		
Ehrlich	16 2	
Orcinol	19 2	12 5[3]
Fucose	0 4	1 5[3]
Uronic acid	0 9	none
$S_{w\,20}$	3 2	3 1[13]
Intrinsic viscosity	0 076	0 069[13]
Partial specific vol	0 714	0 675[13]
Molecular weight	49,000	44,100[13]
$E_{1\mathrm{cm}}$, 1%	6 2	8 0[3]

In conclusion, relatively large amounts of apparently homogeneous bovine orosomucoid were conveniently prepared by the ammonium sulphate–carboxymethyl cellulose method Amino-acid, carbohydrate compositions and the molecular weights of bovine and human orosomucoids were very similar

We thank Dr R Becker, Oak Ridge National Laboratory, for the amino-acid analysis A portion of this work was done while A B was a research associate at the Biology Division, Oak Ridge National Laboratory

Detection and Metabolism of Hydroxychloroquinsulphate and Hydroxychloroquindiphosphate in Human Beings

FOR the long-term treatment of chronic polyarthritis and collagenosis with hydroxychloroquinsulphate (HS) and hydroxychloroquindiphosphate (HP), accurate adjustment to a definite blood-level would be desirable Unfortunately, at the present time, there are no specific methods of quantitative determination which can be used by the clinician for both substances We therefore endeavoured to achieve satisfactory detection of HS and HP by paper chromatography and arrived at the following technique of investigation

(1) *Qualitative detection of HS and HP* Schleicher and Schull filter paper No 2043 B, isopropanol/glacial acetic acid/water (70 15 15), descending paper chromatography After drying at room temperature, tint with platinum iodide reagent (1 1 per cent potassium iodide (Merck) and 0 14 per cent platinum iodide (Merck) added fresh and mixed well in equal parts) After drying at room temperature, HS and HP are visible on a wine-red background as blue-black specks R_F values (mean values of 20

chromatograms of each) for HS, 0 75, for HP, 0 71 Minimum sensitivity of the qualitative detection by means of paper chromatography 5γ for both substances Both substances fluoresce markedly in ultra-violet light even before being dyed with a platinum iodide reagent Attempted elution of the blue-black colouring with acetone, ethanol, isopropanol, chloroform or distilled water was unsuccessful However, by parallel testing of both substances at different concentrations, it was possible to arrive at a semi-quantitative estimation

(2) *Metabolism* With oral administration of 200–800 mgm HS and HP to two separate groups, each of five adults suffering from chronic polyarthritis, all the subjects investigated revealed 1–2 further blue-black specks in their serum with R_F values of 0 16 and 0 36 respectively, which were not detectable before administration Even in thousands of other chromatograms tinted with platinum iodide reagent, I was unable to detect these substances spontaneously Allowance must therefore be made for decomposition products of HS and HP Their quantity in the serum is some 5–10 times greater than that of HS and HP 2 hr after oral administration the serum-levels of HS and HP were at their highest It was, roughly, 2–3 mgm per cent, while it was 10–20 mgm per cent in the case of the two decomposition products in question 48 hr after a single oral administration, HS and HP and their decomposition products could still be detected in the serum In the 24-hr urine I found some 1–10 mgm HS and HP, and 30–60 mgm of the decomposition products mentioned

For comparative evaluation of the rate of resorption of HS and HP, I gave two adults with chronic polyarthritis each 400 mgm HS and HP respectively, at intervals of two weeks, and determined the concentration of both substances in the serum 30 min , 2, 24 and 48 hr after oral administration Within 2 hr , the serum concentration of HS was, roughly, three times as great as that of HP

PHYSIOLOGY

Active Transport of Sodium and Chloride by the Isolated Skin of the South American Frog *Leptodactylus ocelatus*

WE have investigated the origin of the short-circuit current[1] in the isolated skin of the local frog *Leptodactylus ocelatus*

It was found that the short-circuit current was invariably and considerably smaller than the net transport of sodium determined with radioisotopes

To explain this difference from previous evidence obtained in other species of frogs, a series of experiments were performed (Table 1) which led to the conclusion that chloride ions are actively transported in the same direction as sodium ions, from the outside to the inside of the skin

If all the chlorides of Ringer solution bathing the skin are replaced by sulphates, a very good agreement between the short-circuit current and sodium influx is found (Table 1) , the current was 94 4–100 8 per cent of sodium influx
